Comparison of the potency of substance P and its analogues on a battery of different bioassay systems is beginning to generate a pattern of activity which may reflect the existence of at least two subclasses of substance P receptors. The clearest demonstration of this derives from studies with the tachykinins, a family of naturally occurring peptides isolated from amphibian skin, which share a common C-terminal amino acid sequence with substance P[4]. For example, substance P is five times more potent than the tachykinin kassinin as a spasmogen in the guinea pig ileum, but is 100–1,000 times less active than kassinin in potentiating the electrically evoked contraction of the rat vas deferens. Iversen and Hanley (MRC Neurochemical Pharmacology Unit) have now extended this analysis to synthetic substance P analogues, including the methyl ester of substance P, which is 10,000 times less active than kassinin on the rat vas deferens but equipotent on the guinea pig ileum[5]. Iversen and Hanley have consequently introduced the terminology SP-P and SP-E receptors to represent these two extremes of biological activity. SP-P receptors predominate in the guinea pig ileum and exhibit greatest selectivity for the methyl ester of substance P and the tachykinin physalaemin. SP-E receptors are present in the rat vas deferens and are activated most potently by the tachykinins eledoisin and kassinin. Synthetic substance P analogues exhibiting specificity for CNS receptors may also exist. Iversen reported that extension of the C-terminal amide group produces an analogue that is ten times more potent than substance P itself in displacing ^{3}H-labelled substance P binding to rat brain membranes but has only one-thousandth its potency on peripheral bioassay systems (Table 1).

The existence of mammalian receptor subtypes that exhibit selectivity for peptides of amphibian or arthropod origin raises the possibility that similar tachykinins may also exist in mammalian species. In fact, Lazarus *et al.* have recently reported low amounts of physalaemin-like peptide in rat brain and intestine[6]. In addition, Keen (University of Bristol) has observed that rat dorsal root ganglia incubated with ^{35}S-methionine can synthesize authentic substance P and also a peptide that is immunoprecipitated by C-terminal- but not N-terminal-specific anti-substance P antisera[7]. Although the identity of this peptide is unknown, these findings suggest that there may be a second

NOTES ABOUT SNAKES

A serpent's first instinctive impulse of self-preservation, like that of every other animal, lies in escape; probably a more nervous creature does not exist. If surprised suddenly, or brought to bay at close quarters, it may be too terror-stricken to attempt flight; then it *bites*, following a curious general rule which seems to obtain throughout nearly the whole animal world, from a passionate child downward, no matter what the natural weapons of offence may be. Young *Felidæ* will keep their talons sheathed until they have exterted all possible force with their soft milk-teeth, and a lizard will seize the hand which restrains it with its insignificant little jaws, when its tail or claws might inflict far more injury. The *Boidæ* never use their constrictive powers in self-defence (unless they are gripped), and it seems probable that if a venomous snake's fangs lay in its tail, it would use its teeth *first* when attacked before bringing them into play.

I was walking in the Botanical Gardens of Rio de Janeiro some time ago, when I found myself literally upon an immense green tree-snake, at least nine or ten feet long. This serpent, of course, was harmless, so that there would have been no danger in grasping it; but it emitted a curious sound in its terror, such as I have never heard before or since. It *screamed*, and so loudly, that some people near, who saw nothing of what was going on, thought they heard a child cry. Serpants make all sorts of noises besides hissing, according to their different kinds; Crotali spring their rattles; the carpet-viper (*Echis carinata*) rubs the imbricated scales of its adjacent coils together; the fer-de-lance (*Trigonocephalus lanceolatus*) is said in St. Lucia to give out a series of little taps with its horny extremity; and many others — such as the rat-snake (*Spilotes variabilis*) of South America — certainly indicate their presence when angry by quivering their tails against the ground; but a crying snake would have been a decided novelty in one's collection.

tachykinin-like peptide within primary sensory neurones. The presence in mammalian species of peptides that may be structurally related to substance P once again emphasizes the need for caution in interpreting immunoassay and immunocytochemical data and justifies the use of such caveats as 'radioimmunoassayable substance P-like immunoreactivity'.

The availability of stable and selective agonists and antagonists is likely to reinforce the existing evidence that substance P is a neurotransmitter in some mammalian sympathetic ganglia. A series of elegant experiments have been performed on the guinea pig inferior mesenteric ganglion (Otsuka, Tokyo Medical and Dental University). In this preparation the organization of preganglionic inputs makes it possible to elicit a pure cholinergic excitatory postsynaptic potential (e.p.s.p.) in postganglionic neurones, by stimulation of preganglionic fibres in the ventral root, whereas stimulation of the dorsal root produces only a slow, non-cholinergic e.p.s.p. (see the figure). Otsuka has shown that the depolarization and changes of membrane resistance that accompany the slow e.p.s.p. can be mimicked by application of substance P[8]. Ultrastructural studies (Cuello, University of Oxford) demonstrated that substance P-immunoreactive fibres in the inferior mesenteric ganglion exhibit classical synaptic specializations at their contacts with the sympathetic neurones. Moreover, there is convincing evidence that these substance P terminals are almost exclusively sensory in origin. When the fluorescent dye, true blue, was injected into the inferior mesenteric ganglion (Höfelt, Karolinska Institute) it was transported retrogradely to sensory neurone cell bodies in the dorsal root ganglion that also contain substance P[9]. The sensory nature of the intraganglionic substance P fibres has been confirmed by Otsuka in electrophysiological studies. Application of capsaicin, which is thought to act selectively on sensory neurones, elicits a slow depolarization of post-ganglionic neurones that is probably mediated by the release of substance P from sensory endings in the ganglion. Furthermore, prolonged application of capsaicin abolishes the non-cholinergic slow e.p.s.p. but does not affect the cholinergic potential or the response to bath application of substance P.

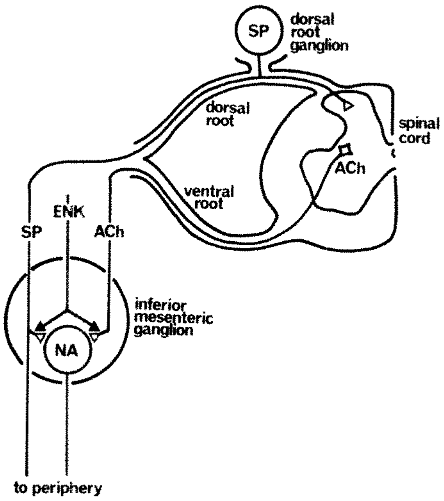

Diagram showing the organization of substance P (SP), acetylcholine (ACh) and enkephalin (ENK) inputs to the guinea pig inferior mesenteric ganglion. Details are given in refs. 8 and 9.

Otsuka also presented evidence that both the fast cholinergic e.p.s.p. and the non-cholinergic slow e.p.s.p. are depressed presynaptically by opioid peptides and that the release of substance P from the ganglion is suppressed by enkephalin[8]. The pharmacological properties of substance P-containing sensory collaterals within the inferior mesenteric ganglion are therefore remarkably similar to those of central sensory terminals in the dorsal horn of the spinal cord, which are also sensitive to capsaicin and opiates. Whether the peripheral processes of the same sensory neurones, which Lembeck (University of Graz) and others reported to be sensitive to capsaicin also respond to opiates is not known.

While substance P in the guinea pig inferior mesenteric ganglion clearly derives from sensory ganglia, the origin of substance P in the rat superior cervical ganglion may be quite different (Black, Cornell University Medical College). When the superior cervical ganglion (SCG) from neonatal rats is removed and maintained in explant culture there is a rapid and dramatic increase in substance P levels within the ganglion[10]. Under these conditions many principal sympathetic neurones exhibit substance P-like immunofluorescence. This is in contrast to the innervated adult SCG where only immunoreactive fibres can be observed, and these are of unknown origin. The increase in ganglionic substance P content in explant culture can be prevented by veratridine, which presumably depolarizes the neurones and releases substance P. Black has, therefore, proposed that in addition to the well established activity-dependent regulation of adrenergic activity in sympathetic ganglia, the peptide content of sympathetic neurones may be modified by activity. However, since decentralization of the SCG *in vivo* results in a very much smaller increase in substance P, other factors must contribute to the enormous increase observed after explantation of immature ganglia.

If substance P can act as a transmitter of slow potentials at synapses formed by sensory terminals in the inferior mesenteric ganglion it may be reasonable to anticipate a similar role for substance P at the central terminals of the same neurones in the dorsal horn. Excitation of dorsal horn neurones following iontophoretic application of substance P (Henry, McGill University) is of a similar duration to that observed by Otsuka in sympathetic ganglia. In a more accessible preparation of spinal neurones in culture, a slow depolarization in response to substance P occurs that may result from a decrease in potassium conductance[11]. While substance P is present in and released from the central terminals of primary afferents in the superficial dorsal horn, physiological evidence

for a sensory transmitter role for substance P has been more difficult to obtain. In fact, the lack of change in C fibre-evoked responses of dorsal horn neurones, after substance P depletion induced by peripheral nerve section, led Wall (University College, London) to question the entire concept that substance P might be a sensory transmitter[12]. Although it seems clear that substance P does decrease substantially in central sensory terminals after peripheral nerve lesions with little immediate change in response to C fibre input, it is not known whether enough substance P remains in the central terminals to maintain a small but releasable pool that is sufficient to exert a postsynaptic action. Given the relatively slow time course of action of substance P on sympathetic and spinal neurones, any depletion of substance P probably leads to gradual and prolonged changes in the excitability of dorsal horn neurones that might be difficult to detect with extracellular recording techniques. Furthermore, as somatostatin will probably also be depleted by peripheral nerve section and inhibits those dorsal horn neurones that are excited by substance P, the net change in postsynaptic response may be even more subtle. It is, however, important to emphasize that the evidence in favour of substance P as an afferent transmitter in the dorsal horn is still tenuous — although at present there are no compelling suggestions for alternative roles. By analogy with the inferior mesenteric ganglion, it is possible that substance P acts on dorsal horn neurones that also receive input from primary afferents releasing a more rapidly acting sensory transmitter. Once again, an effective receptor antagonist would go some way to resolving these problems.

Finally, in any symposium devoted to a single peptide, there is the danger of becoming a little myopic. Recent immunocytochemical studies on the retina and on enteric neurones, for example, have revealed that substance P is found in only about 10 per cent of the total population of peptide-containing neurones, in similar or the same classes of cell that are often functionally indistinguishable. In these systems the appreciation of a specific function for substance P may still be some way off. It is more encouraging to reflect that many of the chemical probes necessary for analysing substance P system will at least be available by that time. □

The unregenerate nervous system

from Miranda Robertson

CUT the optic nerve of a frog, or the spinal cord of a fish, and within weeks the frog will see and the fish will swim again; the same lesions in a man will cause irreversible blindness and paraplegia. Must man, in common with other mammals, accept the loss, or can the regenerative capacity of his central neurones be reawakened? This question was the chief common focus of participants at a recent meeting in Berlin*, where neurobiologists discussed with clinical neurologists individual interests ranging from the control of development in intact invertebrate nervous systems to the control of oedema in damaged human ones.

The central problems have not changed since the time of Cajal, who in the 1920s clearly perceived that the two prerequisites for effective repair in the central nervous system of higher vertebrates were signals for axon growth and signals for axon guidance, both apparently lost at maturity. In this the mammalian central nervous system differs not only from the central nervous system of lower vertebrates, but from the mammalian peripheral nervous system, in which cut nerves do regrow. The question is, why? Interest very early focused on the differences between central and peripheral glial cells: whereas peripheral glia tend to form a tunnel through which a growing axon may extend, central glia at the site of a lesion form an apparently impenetrable scar. This observation led Tello, working in Cajal's laboratory in 1911, to test the effect of inserting a segment of sciatic nerve containing healthy proliferating glia into a deep incision in the cerebral cortex of a rabbit. This procedure induced vigorous sprouting of the ordinarily recalcitrant central neurones into the grafted nerve, even across glial scar tissue of central origin[1].

The excitement evidently felt by Cajal at this discovery found an echo 70 years later in Berlin, where A. Aguayo (Montreal General Hospital) aroused considerable interest with reports of his own recent work, identical in principle with Tello's but with some important technical refinements. Foremost of these has been the use of horseradish peroxidase to establish unequivocally the central origin of the regenerating fibres, and thus eliminate the possibility — later raised in connection with Tello's results — that they derived from the sympathetic nerves innervating cerebral blood vessels. Aguayo and his colleagues have thus been able to show that grafts of sciatic nerve in spinal cord[2], brainstem[3] and cortex[4] can induce sprouting of adult neurones for up to 2 cm, which is probably more than most central axons ever attain in normal development. The importance of this finding, as Cajal recognized, is that it clearly shows that the capacity for axon growth is not irretrievably lost in differentiated central neurones, and that the behaviour of adult neurones, like that of embryonic ones, may still be influenced by their environment.

Indeed, the identification of the environmental tropic factors that determine the developmental fate of neurones has become one of the major preoccupations of neurobiology. So far, the only factor to have been purified and characterized is nerve growth factor (NGF), which is required for the growth and development of sensory and sympathetic neurones and has been implicated in the regeneration of some nerves[5]. It has, however, proved technically difficult to demonstrate NGF in the nervous system, although the presence of specific NGF receptors has been shown on several types of neurone (H. Theonen, Max-Planck-Institut, Martinsreid).

It is notorious that NGF would probably have remained undiscovered to this day but for the series of lucky accidents and inspired guesswork that led R. Levi-Montalcini to the male mouse salivary gland which, for reasons that are still entirely opaque, is full of it. In the absence of an equivalent fortuitous source, it should not be surprising that other factors, identified through their effects on cultured cells, have remained largely elusive. A new one, which may have some bearing on the influence of the glial environment, has been discovered by Thoenen in a crude extract of pig brain. It seems to be a basic protein with two interesting effects on dorsal root ganglion cells *in vitro*: it enhances their survival, and it substantially reduces their ability to bind NGF. The glial origin of the factor is inferred from the correlation between the proportion of glial tissue in the brain and the relative amount of factor that can be extracted from it. The existence of a factor that enhances neuronal survival could clearly be of considerable interest, particularly since it is specific for a subpopulation of cells whose survival is not enhanced by NGF. But it is not yet known whether it acts *in vivo*.

The effect of the factor on NGF receptors may be of even greater interest: it is still not clear how far changes in neuronal behaviour with maturity are due to the disappearance of growth signals, and how far to the loss of receptors for the signalling molecules. While it has now been shown that adult central axons can be induced to

grow, it has not yet been demonstrated that they can be guided to the appropriate targets, and it remains possible that those factors that drive them to terminal differentiation also blind them for ever to the signals that directed their earlier growth.

To unleash the extension of such undirected axons would, as Aguayo acknowledged and R.W. Gilliatt (Institute of Neurology, London) repeatedly emphasized, be to invite consequences far more hideous than paraplegia. Gilliatt's experience is with peripheral nerve injuries. Although peripheral nerves regrow, they seldom do so perfectly: a patient with damage to the brachial plexus in the shoulder, for example, will never regain the full use of his hand. And even where the damage is more limited, aberrant reinnervation — or worse, correct reinnervation accompanied by aberrant collateral innervation — may cause pain and malfunction more serious than the original loss. Hence the need to know not only what induces the growth of fibres but what guides them to their targets and determines what they do when they arrive.

The most resplendent example of functional reinnervation after injury is probably that of the amphibian optic nerve, which is able to regenerate to a topologically precise array of connections on the optic tectum. If such precise reconnection can be induced in a frog, might if not in principle be inducible in man? E. Frank (Harvard University) argued that the limiting factor might be size: morphogenetic signals that can operate efficiently in embryos and frogs might have too short a range to work properly in adult man. But while this is a perfectly reasonable supposition, it is quite inadequate to account for the differences in the regenerative capacities of different species. Mice, which are tiny, are as badly off as we are, whereas bullfrogs (S.S. Easter, University of Michigan, pointed out), can be enormous but can still re-establish accurate connections.

In fact, it is becoming increasingly clear that there can be profound differences in the morphogenetic flexibility even of the embryos of different species. These differences first came to light as discrepancies in the data on the specification of retino-tectal connections in chicks on the one hand and amphibia on the other. Broadly speaking, if the eye of a frog or a kitten is damaged early enough, nerve fibres from the undamaged tissue will spread out to innervate the vacant space. In chicks, however, no such adjustment takes place; the space remains vacant and the denervated neurones die. More recent data, reported by J.K.S. Jansen (University of Oslo), provide further evidence that this reflects a real difference in the developmental plasticity of the different species. Jansen has tested the monosynaptic reflexes of chicks after removal of a small segment of the neural crest that supplies the sensory component of the reflex, and finds permanent sensory denervation of the target muscle[6].

In an equivalent experiment on the developing frog, Frank removed the single dorsal root ganglion that supplies the sensory innervation of the forelimb, and found by contrast that the mature frog had normal monosynaptic reflexes. He also found that the ganglion adjacent to the ablated one was enlarged, and concluded that sensory neurones in the enlarged ganglion had established both the central and the peripheral connections appropriate to the forelimb[7]. Plainly the larval frog nervous system retains a plasticity that is lost at a much earlier stage of development in the chick.

There may, however, be insuperable obstacles to the recapitulation of the processes leading to functional reinnervation in a similarly damaged adult. The obstacles lie in the probable mechanisms of developmental specificity. Frank, for example, offers two explanations for his results. One possibility is that the enlarged ganglion at the time of the lesion still contains undetermined cells which proliferate and adopt the specification of the missing cells. The other is that cells with the appropriate specification were already present in the ganglion, where they would ordinarily have been eliminated in competition with the existing correct ganglion cells. In either case, the replacement cells would no longer be available in an adult.

There is already evidence in other systems that specificity of neuronal connections is brought about by competitive and other interactions between cells whose initial specification may be relatively coarse and graded rather than precise and discrete. One case in point seems to be the specification of the spinal nerves innervating the sympathetic ganglia of guinea pigs[8]. Thoracic or lumbar ganglia transplanted into the normal site of the superior cervical ganglion will attract innervation from a far higher proportion of more caudal roots than would normally innervate cells at the level of the superior cervical ganglion. J.R. Sanes (Washington University) has recently shown a similar gradient in the reinnervation of intercostal muscle transplanted from two different levels of the thorax to the level of the superior cervical ganglion: while both grafts attracted a broad spectrum of innervation, the main source was significantly more caudal for the more caudal graft.

The gradients of overlapping specificities implicit in these results, however, are seldom characteristic of the innervation pattern of nerves at their final destinations. Developing motor nerves arriving at the periphery undergo ruthless pruning that involves the death of some cells and the withdrawal of many terminals; central nerves arriving at the visual cortex of binocular mammals segregate into a pattern of alternating stripes representing the input from the two eyes. In both cases, there is compelling evidence that the patterning depends on activity in the nerves. If all the neuromuscular junctions in a chick embryo are silenced with curare or α-cobra-toxin, the normal process of selective motor neurone death does not occur at the usual time; and conversely, it can be accelerated by electrical stimulation of the limb[10]. In the visual cortex, the segregation of the inputs from the two eyes fails if the optic nerves are silenced with tetrodotoxin[11]. Exactly how activity determines the pattern of connections is not known; but plainly where cell death is involved it is unlikely that regeneration will be capable of reproducing the specificity of the original. (On the other hand, a regenerating peripheral nerve may have the advantage of indelible footprints left by its predecessor. In particular, the Schwann cell sheath round the distal stump of a severed axon may guide the regenerating fibre in the general direction of its target, and there is now a great deal of evidence that the re-establishment of neuromuscular junctions is directed by molecules inserted in the basal lamina of the muscle at the site of the synapse[12].)

In general, however, if cell death is a part of development then cell growth may be a necessary part of perfect regeneration. It is probably significant that in those species in which central nerves regenerate, the neural tissues continue to grow in adult life. The retina of the frog and fish, for example, continue to recruit new cells indefinitely. It may also be significant that animals whose central nervous systems regenerate never make very sophisticated use of them. If a frog's eye is inverted before it is allowed to rejoin to the tectum, the frog never learns to adjust to the rotated image. A man, similarly handicapped by means of inverting lenses, can — at least up to a point. Possibly the loss of developmental plasticity is the price mammals have paid for the synaptic plasticity that enables us to learn. Why such a loss should be the concomitant of an increase in synaptic plasticity, however, we shall be unable to guess at until we understand learning. In the meantime, we are left with Cajal's verdict of more than half a century ago: ". . . in adult centres the nerve paths are something fixed, ended, immutable. Everything may die, nothing may be regenerated. It is for the science of the future to change, if possible, this harsh decree." □

What role for autologous marrow transplantation in cancer therapy?

from Rainer Storb

Toxicity to the marrow is a serious limitation of cancer therapy due to the vulnerability of the rapidly dividing haematopoietic stem cells to the anti-cancer agents. Higher — and potentially curative — doses of chemoradiotherapy may be possible when they are given in conjunction with replacement of the marrow by transplantation. However, because the donor marrow must be free of all tumour cells the graft has had to come from a separate, healthy individual — raising all the problems of immunological compatibility and restricting treatment to those with suitable donors, either an identical twin or a histocompatible sibling. A way round this restriction would be possible if marrow could be taken from the affected individual before chemoradio therapy and cleared of tumour cells without destroying the haematopoietic cells. In this issue of *Nature* Krolick and his colleagues report some preliminary successes in mice using an antibody–toxin conjugate to purge marrow of tumour cells.

In general, for marrow grafting to be effective, two requirements must be fulfilled. First, tumours must be responsive to a short burst of high-dose therapy. Candidate tumours are leukemias and lymphomas, oat cell carcinoma of the lung, carcinoma of the breast, testis and ovary, soft-tissue sarcomas and pediatric malignancies such as neuroblastoma and Wilm's tumour. Second, as pointed out above, the infused marrow must be free of clonogenic tumour, for otherwise, tumour would recur from cells transferred with the marrow even when the body burden of tumour has been eradicated.

Much has been learned about tumour responsiveness from aggressive high-dose chemoradiotherapy of haematological malignancies using 'rescue' with healthy marrow either from an identical twin — a syngeneic graft — or from a sibling identical at the major histocompatibility complex — an HLA-identical allogeneic graft[1-5]. Success has been most impressive in patients with acute nonlymphoblastic leukaemia (ANL) grafted in first remission, with a long-term disease-free survival rate of 55–60 per cent and relapse rates of 10 per cent after allogeneic grafts. The survival rate in patients with ANL grafted in relapse or second remission has been 25 per cent, with a relapse rate of 50 per cent. These rates compare with a survival rate of 20 per cent and a relapse rate of 70–80 per cent in patients with acute lymphoblastic leukaemia (ALL) grafted in relapse or second remission. Results in non-Hodgkin's lymphoma are limited, but perhaps 50 per cent disease-free survival can be achieved. Relapse rates were significantly lower after allogeneic than after syngeneic grafts, perhaps because graft-versus-host disease contributed an antileukaemic effect[6]. Relapses originated almost exclusively in cells of host origin. Clearly, the problem of eradicating leukaemia has not yet been solved.

Nevertheless, the relative success of syngeneic and allogeneic marrow transplantation and the availability of effective cryopreservation techniques have stimulated research in autologous transplantation[7] — transplantation of bone marrow within the individual. The major limitation in syngeneic and allogeneic transplantation is that only 25–40 per cent of all patients have suitable donors. The use of autologous marrow would extend high-dose therapy to larger groups of patients and avoid graft-versus-host disease.

To achieve results with autologous marrow grafting comparable to those with syngeneic or allogeneic grafts the marrow must be cleaned of contaminating tumour cells without destroying haematopoietic stem cells. A number of laboratories have shown that this can be accomplished in certain rodent tumours using *in vitro* treatment with cytotoxic drugs or immune reagents. The latter have usually been absorbed antisera from a different species cytotoxic to the tumour but not to haematopoietic stem cells. In most experiments, haematopoietic cells were first contaminated with syngeneic tumour cells and then incubated with antibody and complement before infusion into a lethally irradiated syngeneic recipient. Successful elimination of murine T cell AKR/J leukaemia and of, 6C3HED lymphoma with haematological restoration of the recipients have been reported[8,9]. Initial attempts have been described to apply *in vitro* treatment with antibody and complement to autologous human marrow grafts for common ALL[10].

Unfortunately, cell killing by antibody and complement is incomplete, and 5–10 per cent of tumour cells can be predicted to survive. Moreover, the quality of complement is variable. These problems with the conventional antibody plus complement approach emphasize the importance of the report by Krolick *et al.* (p.604) on the selective killing of leukaemia cells of the murine B-cell tumour, BCL$_1$, by antibody–toxin conjugates. They have treated $1\text{–}10 \times 10^5$ spleen cells from mice-bearing BCL$_1$, 80 per cent of which were estimated to be tumour cells, with rabbit anti-mouse immunoglobulin antibody coupled with the A chain of the natural toxin ricin. From studies of cell transfers, they conclude that less than ten viable tumour cells remain in the spleen cell inocula. They then showed that antibody–ricin treatment could be used to 'purge' marrow from BCL$_1$ tumour cells. Transplanted mice observed for 6 weeks did not show tumour although haematopoiesis was restored.

Encouraging as these results are, they must be interpreted with caution. First, the observation period of six weeks is short not only by human but also by murine standards. Leukaemic relapse has been seen as late as three and a half years after allogeneic human marrow grafting. Second, as the authors themselves point out, the BCL$_1$ tumour consists almost entirely of cells expressing surface immunoglobulin and does not possess a major pre-B cell component, a quality perhaps not shared by human leukaemias.

Experimental animal tumours may be more mature because they are often perpetuated by way of passaging. In contrast, spontaneous human leukaemias may originate from stem cells closely resembling normal haematopoietic stem cells and not expressing the differentiation antigens characteristic of their leukaemic progeny. Indeed, studies using the marker glucose-6-phosphate dehydrogenase have suggested that ANL may involve stem cells capable of differentiating into granulocytes–monocytes, platelets and erythrocytes[11]. Thus, despite complete removal of recognizable leukaemic cells from a marrow inoculum by antibody–ricin conjugate, leukaemia might recur from infused leukaemic stem cells.

Despite these reservations, clinical studies should be undertaken. Monoclonal and polyvalent antibodies are now available that react with a variety of human tumour cells, including non-T cell ALL, T cell ALL, non-Hodgkin's lymphoma and ANL[12]. The results of syngeneic and allogeneic marrow transplantation will serve as the yardstick by which the potential of autologous transplantation can be measured. ☐

Quasars resolved?

from M.G. Edmunds

SOME controversies seem to go on for ever, but the quasar redshift debate must surely soon come to an end. During the past year the arguments for interpreting the redshifts as an indicator of large distances to the quasars have grown stronger, despite a spirited rearguard action by the main champion of a non-cosmological interpretation.

In a recent paper in the *Astrophysical Journal*[1], Arp reports the discovery of several new quasars which lie in directions close to galaxies not very far away in space from our own Galaxy. Arp has maintained that there is evidence for a considerable excess in the number of quasars per unit area of sky around nearby galaxies (as seen from Earth), compared with regions away from obvious galaxies. He has suggested that this supports the idea that quasars are objects ejected by the galaxies, since the conventional 'cosmological' interpretation of redshifts would require an approximately random distribution of quasars on the sky. Arp's latest claim is that around a sample of galaxies which are companions to large nearby spiral galaxies, the observed density of quasars is so high that the probability of the configurations occurring by a chance fluctuation in a random distribution would be an astounding 10^{-17}. If this statistic were right, a cosmological interpretation would be very hard to justify — but the estimate does not stand up to closer examination.

Arp has performed a useful survey in looking at some 34 areas of sky and, although it is unfortunate that he does not give details of the exact area searched in each case, we may use his results to discuss the statistical significance of association. His analysis is to assign a probability of occurrence individually to each association he finds, and then combine these together to obtain an overall likelihood. A rather simpler (and probably preferable) approach is to ask what the expected number of associations would be, given a random distribution and a search of the 34 areas, and compare this with the observed numbers. In his analysed sample Arp finds 13 quasars at an angle of less than 300 arc s from the 34 companion galaxies, and all the quasars are brighter than about 20th magnitude on his magnitude scale. If we assume the search for these objects is complete out to at least 300 s, then if there are on average *n* quasars per square degree the expected number within 300 s of any one galaxy will be of order

$$\pi \times \left(\frac{300}{60 \times 60}\right)^2 \times n,$$

and 34 times this for the total of 34 galaxies sampled. The total predicted is thus $0.74n$. The problem comes in the choice of *n*.

Arp initially assumes 10 per square degree down to 20th magnitude, giving a predicted number of 7 against an observed 13, which is perhaps a larger fluctuation than could reasonably be ascribed to chance (although not a fluctuation with as small a chance as 10^{-17}). But it is not obvious that 10 is the correct value to take for *n*. By assuming instead 18 per square degree down to 20th magnitude observed and predicted values can be made to agree, and as emphasized by Véron and Véron[2], a reconsideration of all available data on quasar densities shows that such an assumption is not unreasonable. Osmer[3] found 14 per square degree down to 19.75 magnitude. Véron and Véron suggest that the major problem in the comparison of the various estimates of surface density is the variation of magnitude scales between different observers. Since the observed numbers are a very sensitive function of limiting magnitude, a difference between magnitude estimates propagates very strongly into a difference in surface density. A problem with Arp's statistics is emphasized when he claims that even if *n* were as high as 100, the probability of the associations he observed occuring by change would still be only 10^{-5}, and we note that in this case he should have discovered about 74 quasars within 300 arc s of the galaxies — and indeed the chances of discovering just 13 are very small, but the result would then imply anti-association!

These kinds of statistical argument cannot be considered satisfactory until reasonably large areas of sky have been surveyed completely to a consistent magnitude limit. Arp could fairly argue that most of the quasars he finds are substantially brighter than 20th magnitude (by up to 0.5 magnitude), but again the difficulty arises over variation of magnitude scales — an exactly similar search in 34 areas not centred on companion galaxies would be a useful control sample in setting the relevant (inevitably observer-dependent) value of *n*. Further, neither Arp nor this discussion have taken account of possible enhancement of the surface density of quasars by the brightening of distant quasars by the gravitational lens if the galaxies have massive haloes of stellar mass objects[4].

Strong evidence that most quasars are at the cosmological distances implied by their redshifts has come from the work of two groups, one Canadian[5], the other from the United States and Germany[6]. By definition quasars are 'quasi-stellar' and hence have unresolved circular images on direct photographic plates, although some spatial structure has been recognized in a few cases. What these groups have done is to look carefully at the images of some two dozen low redshift (that is, not too distant) quasars, including the classic 3C273. By scanning both quasars and star images with an accurate measuring machine, they have been able to 'resolve' the quasars by demonstrating that in nearly every case the images of the quasars are more extended than those of stars. The light distribution of these extended images is consistent with their being galaxies — although the data cannot reliably distinguish between the light distribution of a spiral and an elliptical galaxy. Furthermore, the apparent size of the extended image decreases with increasing redshift of the quasar in just the way expected if the underlying galaxies were all of comparable size and the redshift were an indicator of distance.

These results support the idea that what we see as quasars are just the very bright active nuclei of some galaxies. This is not to say that the underlying galaxies are completely normal — the intense radiation source at the centre undoubtedly has some influence on the morphology and evolution of the system. A few of the quasar images are extended into huge jets (as in the case of 3C273) of comparable size to the underlying galaxy — a phenomenon not seen on anything like this scale in normal galaxies — and for a few quasars, the nebulosity around the centre has previously been shown to have the characteristics of highly excited gas.

It must be conceded to Arp that it remains possible that a subset of quasars could have a non-cosmological component to their redshift, although the apparent similarity of nearly all quasar spectra might then be surprising. Apparent alignments of quasar groups on the sky could be interpreted as evidence for physical association of quasars of very different redshifts, and this would be impossible if the redshifts were true distance indicators. However, the statistical simulations of Zuiderwijk[7] confirm previous suggestions that such alignments as are observed are quite likely to arise by chance juxtaposition on the sky, with no physical association.

It was the very considerable spread in the intrinsic luminosity of quasars which vitiated the plotting of a simple magnitude-redshift Hubble diagram that would long ago have settled doubts about their distance. The new information of angular diameter versus redshift of Wyckoff *et al.* must, however, considerably strengthen the cosmological distance interpretation of quasar redshifts. □

Molecular effects in pion capture in complex materials

Daphne F. Jackson, C. A. Lewis* & K. O'Leary
Department of Physics, University of Surrey, Guildford GU2 5XH, UK

G. K. Y. Lam
Batho Biomedical Facility, TRIUMF, Vancouver, Canada

Intensities of X rays from pionic atoms in various materials determine the pion capture ratio in carbon and oxygen. A molecular model with transfer from hydrogen has the features necessary to fit the data whereas the Fermi–Teller law (Z-law) fails. Implications for pion dosimetry and radiotherapy and for studies of molecular structure are noted.

A NEGATIVE pion is a strongly interacting particle, 273 times heavier than an electron. Like any other heavy charged particle, it travels in an almost straight line through material, losing energy by excitation and ionization, and stops at a certain depth which depends on the properties of the material and the incident energy of the pion. Little is known about the capture of stopping pions from the continuum into excited states ofa pionic atom or molecule[1], as this process is simple only in metals when the pion can give up its energy to the conduction electrons[2]. In an isolated pionic atom, the captured pion falls from a highly excited state to lower states by electromagnetic Auger and X-ray processes which are well understood[3].

The influence of the material in which the pionic atom is formed is manifested in several ways. Because the binding energy of a pion is proportional to Z^2, where Z is the atomic number of the nucleus, a pion captured by hydrogen may be transferred to a more tightly bound orbit around a nucleus of higher Z. This means that deexcitation of pionic hydrogen by electromagnetic processes and subsequent nuclear capture of the pion by the proton are in competition with the transfer process. Experimental studies[4,5] have shown that transfer of pions does occur in chemical compounds, mixtures of compounds and gas mixtures. Chemical and physical effects have been observed[5–7] by measuring the intensities of X-ray lines emitted from selected elements in various compounds and mixtures and comparing the ratios of the summed intensities of a series for the same pair of elements in different materials or by comparing the relative intensities of the lines in a series for the same element in different materials.

When a pion reaches the lowest atomic orbits, its distribution overlaps with that of the nucleus. A nuclear interaction can then take place, causing disintegration of the nucleus and emission of short-range charged particles and longer-range neutrons and γ rays[8]. The charged particles are heavily ionizing and their energy is deposited on top of the pion Bragg peak. The neutron spectra produced by pion interactions in carbon and oxygen nuclei are rather similar[9] but the number of charged particles produced by captures on oxygen is less than in captures on carbon and the mean energies are lower[10]. It is therefore important for pion radiotherapy to know accurately the atomic capture probabilities for negative pions on carbon and oxygen atoms. The work by Fowler and Mayes[11] and subsequent dose estimates have assumed the validity of the Fermi–Teller law[2] which predicts that the probability of capture on an atom in a chemical compound is proportional to Z (Z-law). This rule has been shown experimentally to fail quite dramatically in inorganic materials[12,13].

Mesomolecular model

A mesomolecular model of the pion capture process has recently been developed[12–14]. Its essential feature is that the pion may be captured directly into an atomic orbit or may be captured first into a molecular orbit in the vicinity of the valence electrons and subsequently deexcite to an atomic orbit. We have extended the model to include the transfer process from hydrogen[15].

The ratio per molecule of captures on atoms Z_1 to captures on atoms Z_2 is given by[14,15]

$$R=\frac{N_1[n_1+2\nu_1\omega_1+h_1\delta_1 a]}{N_2[n_2+2\nu_2\omega_2+h_2\delta_2 a]} \qquad (1)$$

where N_i is the number of atoms of type i in the molecule, n_i is the number of core electrons, ν_i is the number of valence electrons, ω_i is the probability of de-excitation from the molecular orbit to an atomic orbit of atom Z_i, N_ih_i is the number of hydrogen atoms which are nearest neighbour to (bonded to) a

0028-0836/82/070557—04$01.00

heavier atom Z_i, δ_i is the number of electrons participating in the transfer process and a is the probability per electron of transfer. (This treatment of the core and valence electrons is a simplification, valid for light atoms, of that given in ref. 14.) We have considered $\delta_i = 1$ and $\delta_i = 2\nu_i - 1$ as extreme pictures[15] of the involvement of the valence electrons in the transfer process.

When $a = 0$ and $\omega_1 = \omega_2 = 0.5$, equation (1) yields the Z-law, because $n_i + \nu_i = Z_i$. When $a = 0$ and ω_1, ω_2 are the same for all molecules containing atoms Z_1, Z_2, equation (1) predicts that the relationship between R and N_1/N_2 is a straight line passing through the origin. However, if hydrogen transfer is important or if ω depends on molecular structure, or both, discrepancies from a straight line relationship will be seen. When many different molecules are contained in the material, the values of N_i are determined by dividing the proportion by weight of element i by its atomic weight.

For non-polar chemical bonds the mesomolecular model yields[14]

$$\omega_i = Z_i^2/\Sigma Z_i^2 \qquad (2)$$

and for molecules containing only carbon, oxygen and hydrogen this gives $\omega_C \simeq 0.36$, $\omega_O \simeq 0.64$, $\omega_H \simeq 0$. Because the electronegativity, which is the power of an atom to attract electrons to itself, is different for different atoms, covalent bonds may have a polar character. It has been suggested[14] that this effect will give rise to localization of the pion in the molecular orbital near the most electronegative atom. For a bond Z_1–Z_2, the localization parameters are defined as $p_1 = \frac{1}{2}(1-\sigma)$, $p_2 = \frac{1}{2}(1+\sigma)$, where Z_2 is the most electronegative atom and 100σ is the percentage ionic character of the bond. The probability of capture from a mesomolecular orbit to an atomic orbit of atom Z_i is then given by[14]

$$\omega_i = p_i Z_i^2/\Sigma p_i Z_i^2 \qquad (3)$$

Thus the effect of polarity is to reduce the capture probability for the least electronegative atom and increase it for the most electronegative one.

Outline of the experiment

We have measured the relative intensities of lines in the Balmer series emitted by pionic atoms of carbon and oxygen in a range of materials[15,16]. For some materials we have also measured the intensities of the Balmer series in nitrogen. It is not feasible to study the pionic Lyman series because of the very considerable broadening of the atomic 1s level due to the nuclear absorption of pions from this level. For these light elements the nuclear shifts and widths of the 2p and higher levels are negligible[3], and so is the effect of electron screening.

The experiment was performed with the biomedical pion channel[17] at the TRIUMF Laboratory, Vancouver, using a conventional plastic scintillator counter telescope to detect pions stopping in the target. An additional coincidence was obtained between the stopping signal in the counter telescope and a pion time-of-flight signal to reduce false triggers due to muon or electron contamination or scattered events. X-ray photons emitted from the target were detected using a carefully shielded HPGe detector. Signals from the HPGe detector were accumulated on a 1,024 channel analyser which was calibrated over the range 6–140 keV. Measurements of detector efficiency and resolution were performed over the same range.

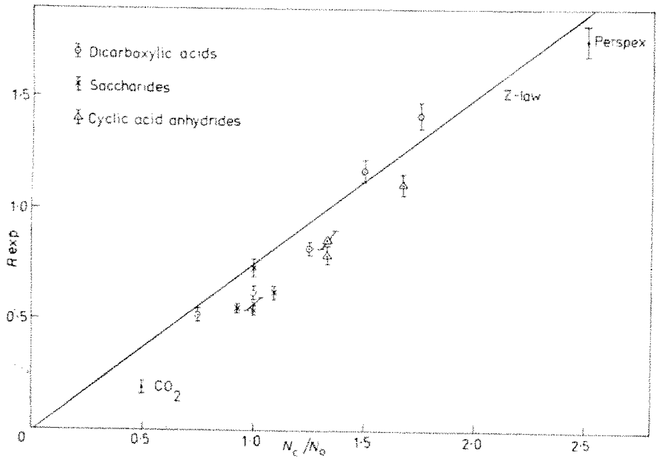

Fig. 2 Experimental results for the C/O capture ratio R plotted against the ratio N_C/N_O of the number of carbon atoms to the number of oxygen atoms.

Table 1 Chemical composition of target materials

Dicarboxylic acids	$COOH(CH_2)_nCOOH$
Malonic acid	$n = 1$
Succinic acid	$n = 2$

Adipic acid	$n = 4$
Pimelic acid	$n = 5$
Cyclic acid anhydrides	
Maleic anhydride	$C_4H_2O_3$
Succinic anhydride	$C_4H_4O_3$
Glutaric anhydride	$C_5H_6O_3$
Saccharides	
D(+) Xylose	$C_5H_{10}O_5$
D(+) Glucose	$C_6H_{12}O_6$
D(+) Mannose	$C_6H_{12}O_6$
Sucrose	$C_{12}H_{22}O_{11}$
D(+) Trehalose dihydrate	$C_{12}H_{22}O_{11} \cdot 2H_2O$
Carbon dioxide (dry ice)	CO_2
Amino acids	$NH_3^+ \cdot CHR.COO^-$
Glycine	R = —H
DL-α-Alanine	$R = —CH_3$
DL-Valine	$R = —CH(CH_3)_2$
DL-Serine	$R = —CH_2OH$
L-Cysteine	$R = —CH_2SH$
Tissue equivalent materials	
Perspex (polymethylmethacrylate)	$(C_5H_8O_2)_n$
Tissue equivalent liquid [19]	Water, glycerol, urea
Tissue equivalent plastic (A150) [19]	Nylon, polymethylene, carbon, calcium fluoride

A typical spectrum is shown in Fig. 1. The principal source of uncertainty in the analysis arose from the determination of the peak areas under the pion lines which were determined using a version of the γ-ray analysis code SAMP O[18]. The main factors influencing the accuracy were the magnitude of the peak intensities and the complexity of the spectrum. In general, the percentage errors in the total intensities for each element, as calculated by SAMP O, were 4–7%. No background subtractions, other than those performed by SAMP O, were needed. The total intensities for nitrogen were subject to much larger errors because the nitrogen content was low and the principal nitrogen line overlapped with a carbon line. It was particularly important to correct the individual X-ray intensities for self-absorption in the target, but the uncertainties introduced by this correction was <1%. The errors shown in Fig. 2 are the standard deviations arising from all sources.

It is assumed that the summed intensities of the lines in the Balmer series is proportional to the atomic capture probability. The validity of this assumption is discussed below.

Choice of target materials

Table 1 lists the target materials and their chemical composition. The rather difficult measurement with dry ice was attempted because it was important to study a molecule containing carbon and oxygen but no hydrogen. However, the main emphasis of the experiment was on the ratio of captures in carbon and oxygen and the effect of hydrogen transfer, and therefore most of the samples consisted of molecules of carbon, oxygen and hydrogen. These molecules were chosen because of their biological importance and also to vary the C/O ratio and the number of OH and CH bonds. The character of the amino acids is strongly influenced by the side-chain R; the form of R for the chosen amino acids is given in Table 1. Certain amino acids and saccharides are strongly lyoluminescent, that is, they emit light when dissolved after irradiation in the dry state, and this property has potential applications in dosimetry. Because of the importance of the results for the pion radiotherapy programme, several targets composed of animal tissues were irradiated. The targets comprised fat, muscle, brain, kidney, liver and lung from a freshly killed pig and samples of fat and muscle from a second pig. The elemental composition of these samples was obtained by chemical analysis before and after irradiation. No significant changes due to irradiation were noted. Several tissue equivalent materials used as muscle substitutes[19], such as perspex, tissue equivalent liquid and tissue equivalent (A150) plastic, were also used. The special features of this part of the experiment are described eleswhere[16].

Results

The experimental ratio R of captures in carbon to captures in oxygen is plotted in Fig. 2 against the ratio N_C/N_O of the number of carbon atoms to the number of oxygen atoms in each molecule, for those molecules containing only C, O and H. It is evident that although the expected trend of increasing capture ratio with increasing N_C/N_O is present, the results do not fall on the same straight line. The Z-law is clearly inadequate. The largest discrepancy is an overestimate of 95% for carbon dioxide. For most, but by no means all, the organic molecules the Z-law gives discrepancies of 20–25%.

The result for carbon dioxide is particularly important because the question of hydrogen transfer does not arise. Using equation (1) with $h_C = h_O = 0$, we find the best value of ω_C to be $\omega_C = 0.19 \pm 0.06$, with the restriction that $\omega_C + \omega_O = 1$. This result is very important as it suggests that equation (2) is not appropriate. The explanation for this result can be found by using the value of the ionicity of the carbon–oxygen bond to obtain the localization factors. For a single bond $\sigma = 0.22$ (ref. 20), which yields $p_C = 0.39$, $p_O = 0.61$ and $\omega_C = 0.26$. But because carbon dioxide contains double bonds, it may be more appropriate to take $\sigma = 0.44$, which yields $p_C = 0.28$, $p_O = 0.72$ and hence $\omega_C = 0.21$. Thus the downward shift of ω_C is a clear indication of the influence of the polarity of the bonds and the sensitivity of the atomic capture ratio to the electronic distribution in the molecule.

Inclusion of hydrogen transfer is not straightforward because we have as yet only plausible pictures of the process and no quantitative theory which predicts the values of the parameters. We have made χ^2 fits to the data, for each group of similar molecules and for the whole set. The parameters were constrained so that $0 \leq \omega_C \leq 1$, $0 \leq a \leq 1$, $\omega_C + \omega_O = 1$. This yields the parameters given in Table 2, with $\delta = 2\nu - 1$. When $(\omega_C + \omega_O)$ is allowed to fall below unity, to allow for a significant value of ω_H, there is no significant change in the results. When $\delta = 1$, the agreement with the data is comparable but in all cases $\omega_C \geq 0.36$ so that this model would not yield agreement with the result for carbon dioxide. If, however, we allow $a > 1$ an overall description can be obtained with a lower value of ω_C. This can be seen from the last line of Table 2 where $\delta_C a_C = \delta_O a_O = 1.77$.

Table 2 Values of ω_C, a_C and a_O obtained by fitting the data and assuming that $\omega_C + \omega_O = 1$, $\delta = 2\nu - 1$

	ω_C	a_C	a_O	χ^2
Acid anhydrides	0.25	0.258	*	0.98
	0.335	0.130	*	0.00
Dicarboxylic acids	0.25	0.340	0.340	2.90
	0.306	0.256	0.256	2.75
	0.325	0.265	0.513	2.75
Saccharides	0.25	0.192	0.192	4.03
	0.375	0.00	0.00	4.00
	0.415	0.00	0.285	3.98
All the above	0.25	0.266	0.266	5.40
	0.263	0.247	0.247	5.39
	0.290	0.254	0.591	4.85

The first row for each group corresponds to the constraints $\omega_C = 0.25$, $a_C = a_O$ and the second row corresponds to the constraint $a_C = a_O$ with ω_C varied. For the third row, all three parameters are varied.

*No transfer occurs to oxygen.

Table 3 Values of R_{exp} divided by R_{theory} for capture ratios in the amino acids

Amino acid target	C/O capture ratio $R_{exp}/R_{Z\text{-law}}$ ($\omega_O = \omega_C = 0.5$, $a = 0$)	$R_{exp}/R_{\text{molecular model}}$ ($\omega_C = 0.25$, $\omega_O = 0.38$, $a_C = 0.16$, $a_O = 0.24$)
Glycine	0.77 ± 0.04	0.85 ± 0.05
Serine	0.77 ± 0.05	1.00 ± 0.06
Cysteine	0.95 ± 0.10	0.97 ± 0.12
Alanine	1.01 ± 0.05	1.04 ± 0.06
Valine	1.11 ± 0.06	1.08 ± 0.06
	N/O capture ratio ($\omega_O = \omega_N = 0.5$, $a = 0$)	($\omega_N = 0.37$, $\omega_O = 0.38$, $a_N = 0.066$)
Glycine	0.95 ± 0.26	0.86 ± 0.23
Serine	1.07 ± 0.28	1.00 ± 0.23
Cysteine	1.59 ± 0.45	—
Alanine	1.21 ± 0.27	1.10 ± 0.25
Valine	1.07 ± 0.23	1.00 ± 0.21

The results for perspex and TE liquid can be reproduced exactly with $\omega_C = 0.25$, $a_C = a_O = 0.21$, whereas the Z-law prediction is too high in both cases. The values $\omega_C = 0.25$, $a_C = 0.266$ give excellent agreement[21] with experimental results for cellulose acetate and mylar obtained at SIN, Zurich[22].

For the amino acids, we have used the value $\omega_C = 0.25$ deduced as an average value for other molecules (see Table 2). Quite good agreement for the C/O capture ratio is then obtained with $\omega_O = 0.38$, $a_C = 0.16$, $a_O = 0.24$, as can be seen from Table 3. Assuming that $\sum_i \omega_i = 1$, we infer that $\omega_N = 0.37$ for the amino acids containing C, N, O, and H only (excluding cysteine). This yields excellent agreement with the data for the N/O capture ratios, with $a_N = 0.066$.

The results for the C/O capture ratio in the muscle samples from the two pigs are in very good agreement. The results for the fat samples are quite different because the samples represent different kinds of fat from different parts of the animal. The sample of subcutaneous fat, which may contain muscle fragments, gave results consistent with the other tissues[16]. Taking the average of the C/O capture ratios for the tissue samples, we obtain

$$R_{exp} \simeq 0.58 R_{Z\text{-law}}.$$

Inserting this value into equation (1), neglecting hydrogen transfer and assuming $\omega_C + \omega_O \simeq 1$ (the nitrogen content is low), we obtain $\omega_C = 0.23 \pm 0.04$ which is in good agreement with the results for the organic molecules. The tissue equivalent materials give quite different results for the C/O capture ratio in the sense that $R_{exp}/R_{Z\text{-law}}$ is 0.82 (TE liquid), 0.96 (perspex) and 1.66 (TE plastic).

The large deviations from the Z-law for cysteine, TE plastic and pig tissues are almost certainly due to the presence of additional elements, such as S(cysteine), F, Ca (TE plastic), minor and trace elements (tissues).

Comparison with muon data

Similar measurements have previously been made with muons[8,12,13,23,24] and also show significant departures from the Z-law. Because muons are not strongly interacting, the data are generally easier to interpret. However, there are reasons why the capture ratios for pions and muons may not be identical. We have assumed that the summed intensity of the Balmer series is proportional to the total capture probability for a particular element, while for muons it is assumed that the same is true for the Lyman series. Both assumptions will be valid if the cascade process leads to a low population of the 2s state and higher np states ($n > 2$). Cascade calculations for isolated atoms confirm that this is indeed the case, but formation of molecular orbitals could change the selection rules at the beginning of the cascade.

(Theoretical investigation of this point is in progress.) But to produce any significant error in our assumption, the effect would need to be significantly different in carbon and oxygen and there is experimental evidence that this is not the case for pions (H. Koch, personal communication quoted in ref. 22). There is also the more important possibility that direct nuclear capture of pions by hydrogen can occur from highly excited molecular states[12,13]. The contribution of transfer of pions from hydrogen to heavier atoms would then be reduced in comparison to transfer of muons.

From previous measurements[23] of muon capture in tissues and tissue equivalent materials we have taken the concept of transfer from hydrogen to the nearest heavier atom but the particular model used, with $\delta = 1$, does not give the best description of our data. Furthermore, there is a factor of three discrepancy between the muon results reported for pig fat[23,24]. A detailed comparion with the pion and muon data, including muon measurements made as part of our experiment, are given elsewhere[16] and indicate that there are sufficient differences to make this detailed study of pion data necessary.

Discussion

The results for tissues and tissue equivalent materials are of considerable practical importance because the ratio of captures in carbon to captures in oxygen in real tissues is very much less than has hitherto been assumed. Our results confirm the suggestion[25] that materials which are tissue equivalent to X rays, electrons and neutrons are not tissue equivalent for pions. This is clearly due to major differences in molecular structure. Hitherto, only atomic and nuclear properties, such as electron density, effective atomic number and neutron cross-section, have been taken into account in defining tissue equivalence.

The Z-law, and its variations, fail to fit the data. The mesomolecular model contains an essential new feature[13]—the redistribution of the contribution of the valence electrons—because in general $n_i + 2\nu_1\omega_1 \neq Z_i$. The probability ω for atomic capture from the molecular orbit is not proportional to Z^2; instead it seems that ω is sensitive to the electronic structure of the molecule in a manner which relates to the localization of the mesomolecular orbital near to atoms of high electronegativity.

Hydrogen transfer is essential for a quantitative description of the data. The choice $\delta = 2\nu - 1$ may be preferred and different transfer parameters for CH and OH bonds may be indicated. Clearly the transfer parameter a is very sensitive to molecular structure but further work will be needed to give complete understanding of the transfer mechanism.

It had been suggested that muonic X-ray analysis can be used for bulk elemental analysis[23]. Our results suggest, in contrast, that pion capture (and probably also muon capture) is a sensitive means of probing molecular structure in complex materials. It should be very sensitive to changes brought about by substitution of one atom by another of a different element or when bonds are broken, for example, by radiation damage.

We thank the SRC for support to C.A.L. and K. O'L. and for visits by the Surrey team to Vancouver. We thank the director and staff of the TRIUMF Laboratory and the Batho Biomedical Facility, Vancouver, for the facilities and assistance provided, and particularly R. W. Harrison. We also thank the muon physics group of the University of Victoria, Canada, for the loan of equipment.

How honey bees use landmarks to guide their return to a food source

B. A. Cartwright & T. S. Collett
School of Biological Sciences, University of Sussex, Brighton BN1 9QG, UK

Bees trained to forage at a place specified by landmarks do not construct a cartesian map of the arrangement of landmarks and food source. Instead they store something like a two-dimensional snapshot of their surroundings taken from the food source. To return there, bees move so as to reduce discrepancies between the snapshot and their current retinal image. A computational model embodying these principles mimics the bees' behaviour.

HONEY BEES can learn the position of a source of sugar by reference to nearby landmarks (reviewed in ref. 1). We describe here what bees seem to learn about the spatial layout of landmarks and how this information might guide their approach to the source. Our experimental results strongly support earlier proposals[1-4] that to identify a place to which it will return an insect learns no more than the appearance of the landmarks viewed from that spot—just as though it takes and stores a panoramic snapshot of the landmarks from that position. Then, to find its way back, it compares the image on its retina with the stored snapshot and moves until the two match. It is not immediately obvious that this hypothesis can work, and we have therefore developed a computational model to show that it does.

Bee tests

Single marked bees were trained to fly through an open window into an experimental room (floor area 4 m × 4 m) to collect sugar

0028-0836/82/070560—05$01.00

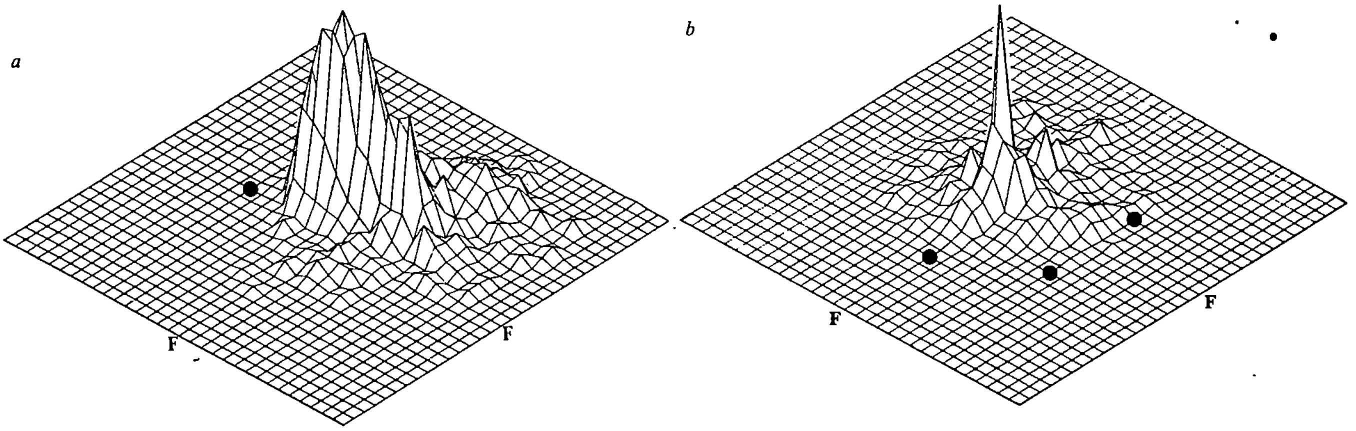

Fig. 1 *a*, Distribution of a single bee's flight time within the area surveyed by the camera when trained to a food source 50 cm from a single cylindrical landmark and tested with the same-sized landmark (4 cm diameter and 40 cm high). The position of the food source during training is marked by 'F' on the *x* and *y* axes. The position of the base of the landmark is indicated by filled circles. Height shows relative times spent in different regions of the testing area. Lines on grid are 8.7 cm apart. *b*, Distribution of bee's flight time when trained and tested with three landmarks in the standard array described in Fig. 2.

solution from a small reservoir (diameter 1.5 cm) on the floor. The room was painted entirely white, except for random green markings on the floor to help the bee stabilize its flight, and the window was covered by white sheeting. The location of the reservoir was indicated by the position of one or three matt black cylindrical landmarks standing upright on the floor. The bee returned to the room every 5 to 10 minutes. To encourage the bee to associate the food source with the landmarks, between visits the whole arrangement of cylinders and reservoir was shifted in register to a new position, without changing its orientation.

After a day of training with a standard array, tests were conducted at ~40-min intervals. The food source was then removed and the flight path of the bee recorded for 2 min by an overhead video camera suspended on runners fixed to the ceiling. The camera surveyed an area of floor 2.7 m×2.7 m centred on the position of the missing reservoir, and the testing site was varied systematically within the room. Sometimes the size, number or spatial arrangement of landmarks was altered between training and the subsequent test. An individual bee was given several types of test, each replicated 5–10 times. Each type of test was conducted on at least two bees.

The position of a bee was recorded every 100 ms from the video tape and the results from 5–10 tests of the same type are combined to show in Figs 1 and 2 how an individual bee distributed its time in the vicinity of the landmark array. Our aim was to infer from the bee's searching pattern where it thought the reservoir was to be found, and from this to deduce what it knew about the arrangement of landmarks.

When a bee was trained to a food source at a constant distance from a single cylindrical landmark, and then tested with the food source removed, it searched roughly where it had previously foraged with respect to the landmark (Fig. 1*a*). Although a radially symmetrical landmark does not define direction, the bee does not fly in a circle around the landmark, implying that some other cue (possibly the window) must specify in which direction from the landmark the food lay. Tests with single landmarks smaller (or larger) than the training size result in a search area shifted closer to (or further from) the landmark (ref. 5 and B.A.C. and T.S.C., in preparation). This suggests that the bee has not learnt the distance between landmark and food source but rather how large the landmark appears when viewed from the food source, and also that to find the reservoir the bee flies to where the image of the landmark on the retina is of the right size.

Experiments using three landmarks, when the search area is rather more sharply defined (Fig. 1*b*), reinforce these conclusions. If a bee is trained to a particular configuration of landmarks and then tested with a different spatial arrangement of those same landmarks, it always searches in an area where the inter-landmark angles (as shown in Fig. 2) are the same as when seen from the food source. The actual distances of the landmarks from each other or from the search area are of minor importance.

Figure 2*a*, *b* shows a bee's search area when it was confronted with an array in which the distances between landmarks differed from those with which it was trained. The bee spent most of its time where the inter-landmark angles matched those experienced during training. Furthermore, if the test configuration was such that a bee could search where either the distances from the landmarks or the inter-landmark angles were correct, it chose to do the latter (Fig. 2*c*).

A bee tested with cylinders that were larger or smaller than the ones used in training also searched where the inter-landmark angle was approximately correct. Figure 2*d* illustrates that this behaviour persists for very dramatic changes of landmark shape and size, when cubes with 30-cm edges were substituted for the training cylinders (4 cm diameter, 40 cm height). We conclude that to a bee the most important feature of the landmark array is the retinal position of the landmarks as seen from the food source.

At first sight, the bees' neglect of landmark size would seem to conflict with their behaviour when they are trained to a single landmark and its size is changed. However, whatever the size of a single test landmark, a bee can always find a position where there is a perfect match between its 'snapshot' and the retinal image of the test landmark. But with three landmarks both their sizes and the distances between them must be changed in a coordinated way for a position to exist where retinal image and snapshot are congruent. If just one of these parameters is varied, then wherever the bee searches there will be some degree of mismatch. Simple geometry suggests that in this case the retinal sizes of landmarks should carry less weight than the angles between them, because the inter-landmark angles are much larger than the angle subtended by the landmark itself. Thus, were the bee to station itself where the angle subtended by one of the landmarks is correct, the positions of the other landmarks on its retina would be very wrong.

It seems, then, that a bee will search within a circumscribed area without requiring a perfect match between its postulated snapshot and its current retinal image. This can be shown in another way by testing bees with landmarks added to or taken away from the training array. Figure 2*e* shows that with two extra landmarks the bee's search area, although slightly larger than normal, is roughly in its usual position. When a bee was tested with any of the three landmarks removed, it still spent most of its time looking where the inter-landmark angle formed by the remaining two landmarks was the same as it was during training (not illustrated). This test also demonstrates that the bee must learn the sizes of the landmarks, for it is only their size that tells the bee whether or not the two remaining landmarks are neighbours and whether the inter-landmark angle should be 60 or 120°.

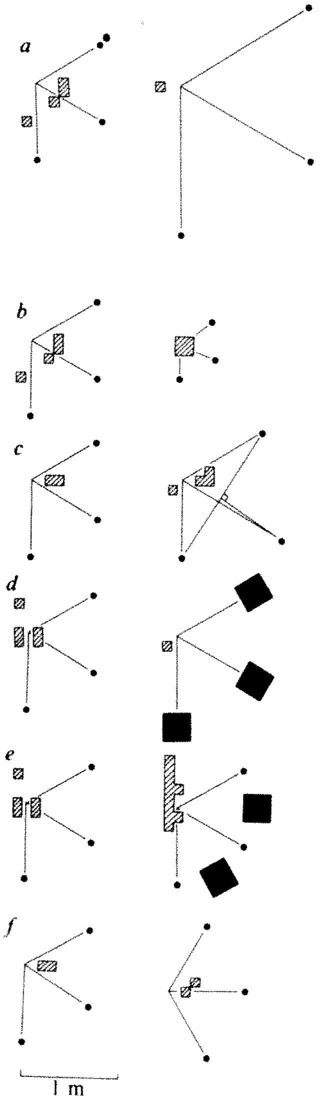

Fig. 2 Tests with three landmarks. The training configuration is shown in plan view in the left-hand column. The food source was placed 76 cm from each landmark at the intersection of the three lines drawn from the landmarks. Inter-landmark angles refer to the angles between these lines. In *a* and *b*, the cylinders were 5 cm in diameter and 50 cm high. In *c* to *f* they were 4 cm × 40 cm. Each row of the figure presents a pair of test arrays. The left half shows where a single bee searched when presented with the training array. On the right is the same bee's search area when presented with a variant of the training array. The hatching represents the search area defined as those squares within the test area (as in Fig. 1) that are at least 80% as high as the peak value. *a*, Distance between landmarks doubled; *b*, distance halved; *c*, landmarks arranged so that bee could search either where the inter-landmark angles or where the distances from the landmarks were the same as during training; *d*, cubes substituted for cylinders; *e*, cubes added to landmark array; *f*, landmark array rotated through 30° from training orientation. The point of intersection of the lines in the right-hand column show where the bee would need to search to see the same inter-landmark angles that it experienced when foraging at the food source. This is generally where the bee spends most of its time.

The snapshot model

All the above findings argue that the representation of landmarks in the bee's memory can be described in terms of a snapshot taken from the food source (see also ref. 1 for somewhat similar experiments on desert ants). The bee does not seem to be equipped with anything akin to a floor plan or cartesian map. We have therefore explored how well a model bee can guide itself using a representation of this kind. The basic idea is that the direction in which the bee moves at any moment is governed by the discrepancy between the snapshot and its current retinal image (Fig. 3).

To construct such a model we must make assumptions about the way images are coded in the visual system and the snapshot. In part these are arbitary. However, we have some evidence that the most important features of the retinal image are the edges between the dark landmarks and the light ground (B.A.C. and T.S.C., in preparation). Accordingly, in the model the retinal image consists of edges lying on a circular retina and the snapshot is represented in a compatible way (Fig. 3). The positions of the edges on both retina and snapshot are defined as compass bearings with respect to Earth-based coordinates. This assumption is supported by several experimental results. First, the tests with single landmarks (Fig. 1*a*) imply that cues external to the landmark specify the direction of the food source from the landmark. Second, when bees were tested with a three-landmark array rotated by 90° from the training orientation, the search area shifted away from the position predicted by the inter-landmark angles experienced during training. Third, bees find it difficult to use landmarks if, during training, the array is rotated between each of the bee's foraging visits. The simplest way to picture how edges in the snapshot can be given Earth-based coordinates is to suppose that the snapshot is fixed in the bee's head and that the bee always maintains the same orientation. This is not in fact so, and one needs to assume that as the bee turns, the snapshot counter-rotates.

Algorithms for calculating flight direction

We have examined two algorithms for generating the bee's direction of flight. These were programmed in Basic and run on a PDP8/a computer. The first, the simplest we could devise, fails to mimic all the bee's behaviour, but the second and more elaborate version performs very much as real bees do.

In the first algorithm (Fig. 4*a*) a unit vector is associated with each edge in the snapshot. The direction of the vector depends on the bearing of the closest edge of the same sign (that is, dark–light or light–dark) on its retina. Imagine each edge in the snapshot putting out an extensible arm to reach the nearest retinal edge. Once the edge is located, a unit vector is generated lying perpendicularly to the bearing of the retinal edge and pointing away from the paired edge in the snapshot, tending thus to align the two edges. These unit vectors are then summed, in the conventional way for adding vectors, to give the bee's flight direction. As the bee moves through the field of landmarks, it will continually update its direction as the edges shift over its retina. Note that it is not necessary for all edges in the retina to be matched to partners in the snapshot. Some may have more than one partner and others none at all. Furthermore, the bee is not required to assess the goodness of fit between its snapshot and the retinal image.

Figure 4*b* shows the computed vector directions for different points within the field of landmarks for a bee which is trained and tested with the same array of three landmarks. If the algorithm is to be successful, then from any starting point the vectors must lead the bee to the food source. The extent to which this is the case is shown in Fig. 4*c*. For most starting points the

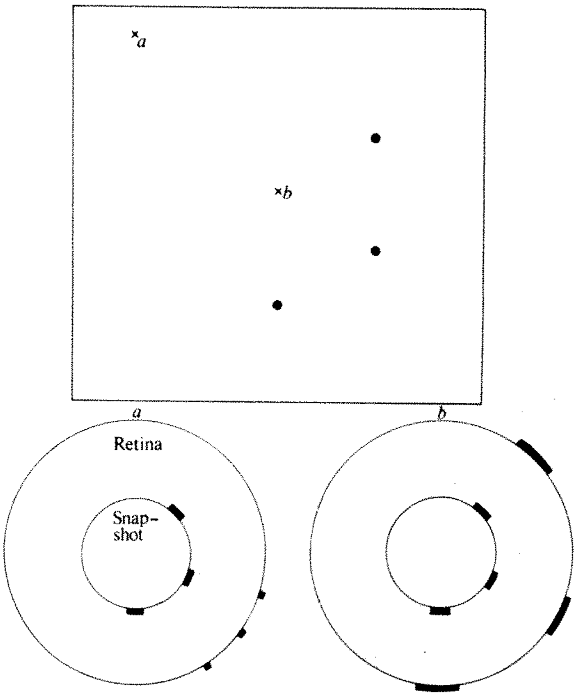

Fig. 3 The snapshot model. Positions of images of landmarks on circular retina (outer circle) and in snapshot (inner circle) viewed from two points within the landmark array as shown by crosses. *a*, Distance from food source; *b*, at food source, where snapshot and retinal image match. The aim of the model is to move the insect from *a* to *b* using the discrepancy between retinal image and snapshot as a guiding cue. Note that positions of edges on the circular snapshot and retina are compass bearings with respect to external coordinates. Frame round landmark array shows area viewed by video camera.

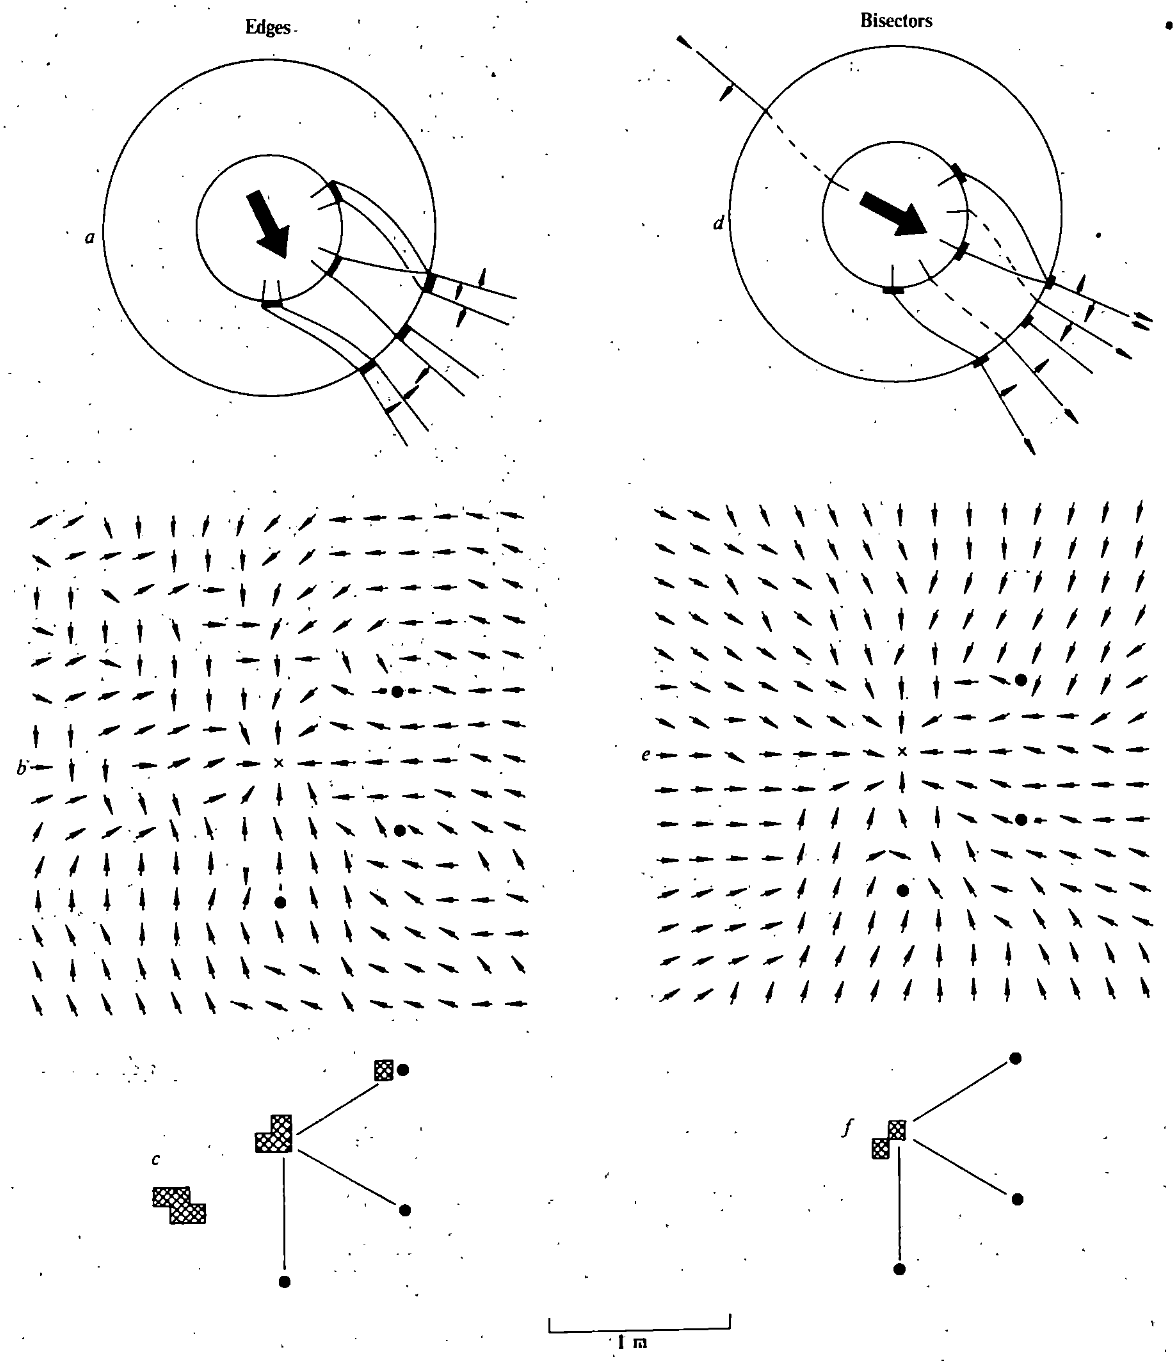

Fig. 4 Two algorithms for transforming retinal image to snapshot. *a*, Edge algorithm. Each edge in snapshot paired with closest edge on retina. Unit vector, shown by arrows around outer circle, is associated with each pair and lies perpendicularly to edge on retina, pointing away from edge in snapshot. Larger arrow in centre of circle shows flight direction of bee obtained by summing the unit vectors. *b*, The flight direction for different positions of the bee within landmark field, computed as outlined in *a*. Model bee trained and tested with landmark configuration of Fig. 3. *c*, Positions of end points are shown by cross-hatching. The bee is started at different positions within the landmark field and it follows the vectors as shown in *b* until it stops. *d*, Bisector algorithm. Unit vectors of positional component shown by arrows lying tangentially to outer circle, those of angular component by radially aligned arrows (details in text). *e*, Vector field for bisector algorithm. *f*, Position of end points for bisector algorithm.

bee does indeed end up at the food source. However, there are mishaps which arise because partial matches exist. There is one position within the field, for instance, where the two outer landmarks form an inter-landmark angle of 60°. The bee is trapped there because within a region on either side the vectors have opposite directions, pointing towards the partial match. Real bees do not make this mistake. The algorithm's performance can be improved if it takes into account the amplitude of the summed vectors. However, it still does not work in all the situations we have tested. In particular it fails if the array of landmarks is rotated by 30° from the orientation to which the bee was trained—a situation with which the bee can cope (Fig. 2*f*). Because the algorithm depends on the positions of edges defined with respect to external coordinates, a changed orientation of the landmark array will generate several points in the field where the edges of two landmarks can be roughly matched with edges in the snapshot, but none where all edges can be correctly matched.

To overcome these problems the second algorithm requires the bee to assess not only the position of each edge, but also the angular distance between them (Fig. 4*d*). Its first step is to decide on the basis of the signs of neighbouring edges whether the angles between them are dark or light. It then measures the size of each dark and light angle in the snapshot and on the retina, and locates the positions of their bisectors. Next, each bisector in the snapshot searches out the closest bisector on the retina with the same sign (dark or light), so pairing angles in the snapshot with angles on the retina. As in the first algorithm, a unit vector (the positional component) is associated with each pair, tending to move the bee perpendicularly to the bearing of the bisector on the retina, pointing away from the bisector in the snapshot (or toward it if the retinal angle is greater than 180°). The additional feature of this algorithm is a second unit vector (an angular component) which depends on the differences between the sizes of the paired angles. This vector faces centripetally along the bisector on the retina if the angle in the snapshot is the smaller, and centrifugally if it is the larger. It thus takes the bee away from retinal angles that are too big and towards those that are too small. All the component vectors are then summed to determine the bee's flight direction, which is shown by the arrow in the centre of Fig. 4*d*.

Figure 4*e* illustrates the directions of the summed vectors within the standard three-landmark array. The improvement over the first algorithm is obvious: there are paths from all points to the food source, and when the bee is flown from different starting points it now always finishes there (Fig. 4*f*). It is easy to see that neither the positional nor the angular component of the summed vector would by itself be sufficient to locate a food source specified by a single landmark, although either can do so when there are three landmarks. With one landmark the positional component defines direction but not distance, so that the bee would search along a line originating at the landmark and passing through the food source. The angular component, on the other hand, only specifies distances and would leave the bee flying in an annulus centred on the landmark. The two acting together are needed to identify the intersecting point.

This algorithm copes with all the one- and three-landmark tests we have tried, including those with landmarks added or deleted. The 30° rotation of the three-landmark configuration on which the first algorithm founders is taken care of by the angular component. However, to prevent aberrant solutions, the angular component must be given a greater weighting than the positional one (3:1), a weighting which works in all situations. When the landmark array was rotated through 90° from the training orientation, the search area was displaced for the model, as it was for real bees.

The algorithm will not only move bees to the right position within an array of landmarks, but it will also bring a bee successfully to a foraging position in the centre of a ring of eight landmarks from points well outside the circle, as in tests with real bees[6].

The model does not specify how directional information is abstracted. The information is assumed to be provided by an independent system. We have attempted, but failed, to generate a simple alternative model in which direction can be automatically obtained from an array of close and distant landmarks.

Despite the success of the model in our artificial environment, it is rash to conclude that this is how bees operate in the real world. For a start, sensory processing is undoubtedly more complicated than we have allowed it to be here. However, what does seem to be certain is that bees do not need a three-dimensional representation of their immediate surroundings in order to use nearby landmarks to locate a food source. A much simpler model will work: one in which the bee is not required to identify landmarks as such, or even to separate figures from the background. There is, of course, a price to be paid for simplifying one's visual world in the way the experiments suggest that the bee has done. It is that the bee can only use the information provided by its snapshot of the landmarks to return to the food source. The snapshot provides it with no means of navigating to anywhere else within the array of landmarks.

Rate of turnover of structural variants in the rDNA gene family of *Drosophila melanogaster*

Enrico S. Coen, John M. Thoday & Gabriel Dover
Department of Genetics, University of Cambridge, Cambridge CB2 3EH, UK

A high degree of polymorphism for the length and copy number of rDNA spacers, in both the X and Y chromosome clusters, has been found in a wild population of Drosophila melanogaster. *The genetic behaviour of rDNA structural variants in separate and mixed populations derived from isofemale lines suggests that they are not subject to strong selection and are stable for over 1,000 generations. The high structural variability suggests an evolutionary rapid process of turnover in the family which could partly explain widespread sequence homogeneity (concerted evolution) of rDNA within a species.*

SEVERAL studies on the evolution of tandem and interspersed repeated DNA families have revealed an unexpected greater family homogeneity within than between species. This phenomenon is known as concerted evolution and has been observed in a wide variety of genic and non-genic families.

The degree and extent of homogeneity in each species cannot easily be understood solely in terms of natural selection and drift, and is more probably the result of molecular mechanisms of homogenization (see refs 1–3 for reviews). Smith[4] and Ohta[5] have described the possible dynamics of homogenization in tandem arrays based on the mechanism of unequal exchange; and others[6–8] have discussed the potential of gene conversion for homogenizing tandem and interspersed families. Mechanisms of homogenization probably have a significant role in shaping the evolutionary progress of a family of genes and it is important to understand the extent and rates of these mechanisms.

Unequal chromatid exchange has been shown to be taking place in the arrays of sequences coding for ribosomal RNA (rDNA) of yeast[9,10] and *Drosophila*[11–13] (for reviews see refs 1, 14–16). In the rDNA of *Xenopus*[15] and *Drosophila*[12], unequal exchange in and between the spacers generates variation in length and copy number of these regions. Using such structural

0028–0836/82/070564—05$01.00

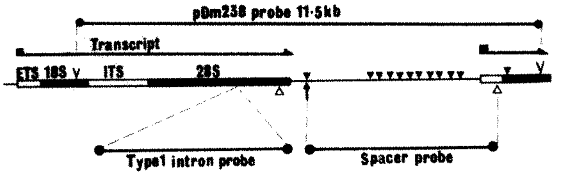

Fig. 1 Map of a repeating unit of ribosomal genes in *D. melanogaster* (see ref. 16 for review). 18S and 28S code for RNAs. ETS and ITS are external and internal transcribed spacers respectively. The nontranscribed spacer (NTS) appears as a line. About 50–60% of rDNA repeats of the X chromosomes have type 1 insertion sequences in the 28S gene. The length and direction of the primary transcript is shown by an arrow. The pDm238 probe is an *Eco*RI fragment cloned into the plasmid pBR322 and was a kind gift of D. Glober[32]. The type 1 intron probe, pC225, contains 5 kb of the type 1 insertion cloned into pBR322 and was constructed by S. Kidd[33]. The spacer probe, pDm103HH2, is a *Hin*dIII/*Hae*III fragment subcloned from cDm103[34] into the plasmid pAT153. The restriction sites are: V, *Eco*RI; Δ, *Hae*III; ↑ *Hin*dIII; ▼, *Alu*I. The position of only those sites in, or flanking, the NTS are shown for *Hae*III, *Hin*dIII and *Alu*I.

features it is possible to assess the rate of unequal exchange and the stability of its products by examining rDNA structural polymorphism in genetically defined populations. Here we present the data on natural variation within and between individual X and Y chromosome rDNA clusters from a population of *D. melanogaster* flies, collected from a single watermelon. We have also examined the genetic progress of each X and Y rDNA type of organization in separate and mixed populations derived from the wild-type founders.

Nontranscribed spacer length and copy number polymorphism in a wild population

In *D. melanogaster* the 18S and 28S rRNA genes are present in 250 tandem repeats in each nucleolus organizer (NO) of the X and Y chromosomes. The organization of the repeating unit is shown in Fig. 1.

The isofemale lines of *D. melanogaster* used in this study are derived from females collected in 1970 from around a single watermelon in Oklahoma (OK. lines)[17]. The first laboratory generation from each female was divided into two sublines—a and b. Analysis of rDNA from females in OK. lines 1 and 19 in 1978 showed differences in restriction pattern between the lines[18].

To examine the full extent of the natural variation we have analysed rDNA organization after 230 generations in each subline for OK. lines 1–10. Variation in length and copy number of the nontranscribed spacer (NTS) was investigated by probing *Hae*III-digested DNA with a NTS cloned probe pDm103HH2 (Fig. 1). *Hae*III restriction of pDm238 produces a 5.1 kilobase (kb) fragment containing an intact NTS together with a small part of the 28S gene and part of the external transcribed spacer (ETS) (Fig. 1). To ensure that only a single NO cluster from each line was being examined, XO male rDNA was analysed by mating single males from the OK. lines to $\hat{X}X/O$ females and collecting the male progeny. *Hae*III digests of XO male DNA from each subline of OK. lines 1–10, probed with NTS clone pDm103HH2, reveal extensive variation between the lines (Fig. 2).

Independent extraction and analysis of XO males derived from the same XY male parent always produced the same *Hae*III pattern, confirming that the variation is not an artefact of partial digestion. *Hin*dIII and *Eco*RI digests suggest that the *Hae*III fragment length variation is due to changes in NTS length (data not shown).

DNA from diploid tissue of larval brains of OK. lines 1a, 2a, 3a and 5a was digested with *Hae*III and probed with the NTS clone. The pattern characteristic of the adults from each line could be identified. Differences between rDNA arrays are not therefore due to differences in polytenization of rDNA units of the sort described by Endow[19].

The contribution of intron-containing repeats to the variation in rDNA organization was investigated by probing *Eco*RI digests with a type I intron clone pC225 (see Fig. 1). Only comparatively small differences were revealed between the OK. lines (data not shown), confirming changes in NTS length and abundance as the major source of polymorphism.

To examine the molecular basis for NTS number and length heterogeneity, a repetitive sequence region in the NTS was investigated by digesting DNA from XO males, carrying the same X chromosomes as analysed in Fig. 2, with *Alu*I (Fig. 1) and hybridizing them to the NTS probe. This experiment revealed the expected 250 base pair (bp) *Alu*I band plus a 1.4 kb band corresponding to the right-hand fragment, and several higher molecular weight bands, presumably from the left of the repetitious *Alu*I region (Fig. 3). The hybridization patterns clearly show that the most abundant lengths of the left- and right-hand flanking sequences fall between 1.4 and 2.4 kb. However, the *Hae*III digests of these chromosomes show that the rDNA from lines 1a, 4a and 9a have some NTS fragments >9 kb long (Fig. 2). The absence of any large right- or left-hand *Alu*I fragments flanking the internal 250 bp repetition in these

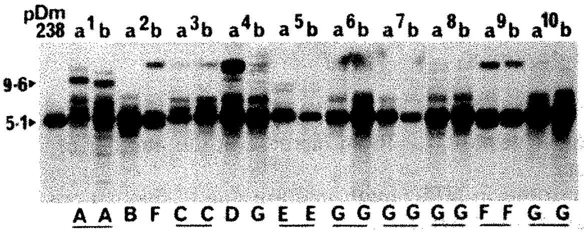

Fig. 2 Hybridization patterns of X chromosome rDNA from the a and b sublines of Oklahoma lines 1–10 in an autoradiograph of *Hae*III digests of XO male DNA that have been fractionated on agarose gels, transferred to nitrocellulose and hybridized to a ^{32}P-labelled clone, pDm103HH2, containing the NTS. Each track contains the DNA of four XO male progeny from a cross between an OK male and an $\hat{X}X/O$ female. The various hybridization patterns have been classified into seven types (A–G). Indistinguishable sublines are underlined. *Hae*III-digested pDm238 hybridized to the same probe is shown on the left for comparison. XO males were constructed by mating OK. males with females from a C(1)A, y/O/Y^{s}XY^{L}, In(1)EN, B y stock obtained from M. Ashburner. Progeny were checked to ensure that all females had a yellow and males a wild-type body colour. Some of the males were also checked for sterility. The remaining males were collected and stored frozen at −70°C for up to 6 months. In all cases DNA was extracted from the flies by a modification of the method of D. Ish-Horowicz (personal communication). Four flies were gently homogenized in a 1.5 ml microfuge tube containing 100 μl of 10 mM Tris, 60 mM NaCl, 5% sucrose, 10 mM EDTA, *p*H 7.5. 100 μl of 1.25% SDS, 0.3 M Tris, 0.1 M EDTA, 5% sucrose, 0.8% diethyl pyrocarbonate (freshly mixed), *p*H 9 were then added. After a 30 min incubation at 65 °C, 30 μl of 8M potassium acetate were added and the mixture kept on ice for 45 min. The precipitate was spun down for 5 min in an Eppendorf centrifuge 5412 and the supernatant added to 2 vol of ethanol. After standing for 5 min at room temperature the ethanol precipitate was spun down for 10 min in the Eppendorf centrifuge and the supernatant discarded. The pellet was resuspended in 100 μl of 0.1 × SSC, 0.2% diethyl pyrocarbonate (freshly mixed) and left to stand at room temperature for 30 min; three volumes of ethanol were then added and the mixture left at room temperature for a further 5 min. The DNA was spun down for 10 min in the Eppendorf centrifuge and washed with 70% ethanol. Residual ethanol was removed by drying the precipitate in a dessicator for 30 min and the DNA was dissolved in 15 μl of 5 mM Tris-HCl, *p*H 7.5, at room temperature overnight. The DNA was digested in a final volume of 25 μl with restriction endonuclease *Hae*III (BRL) after adding 0.2 μg of M13 DNA as a marker and 2 μl of RNase A (Sigma) at 1 mg ml^{-1} (preboiled for 10 min). *Hae*III digests were in 50 mM Tris-HCl, *p*H 7.6, 5 mM MgCl$_2$, 1 mM dithiothreitol. Digestion was with 2–3 U of enzyme for 2 h at 37 °C, followed by 10 min at 65 °C to inactivate the endonuclease. Digests were fractionated on 1% agarose gels using a Tris-borate buffer (Tris 89 mM, boric acid 89 mM, Na$_2$ EDTA 2.5 mM). Gels were stained with ethidium bromide to ensure that digests were complete, and the DNA was transferred to nitrocellulose filters as described elsewhere[35]. Cloned DNA was nick-translated[36] with α-^{32}P-labelled dATP to a specific activity of 10^{8} c.p.m. μg^{-1}. Filters were hybridized with 15 ml of hybridization mixture containing 10^{7} c.p.m. of ^{32}P-labelled cloned DNA after it had been denatured at 100 °C for 10 min. Hybridization conditions were 5 × SSC, 50% formamide, 0.5% SDS at 42 °C overnight with gentle agitation. After hybridization, filters were washed extensively in 3 mM Tris base (unneutralized), dried and autoradiographed.

Table 1 Frequencies of rDNA types in the OK. lines and OK. mixed populations

rDNA type	Frequency in OK. lines	Frequency in OK. mixed	No. of OK. mixed populations 'fixed'
A	0.075	0.03	1
B	0.075	0.13	4
C	0.1	0.10	4
D	0.075	0.13	5
E	0.1	0.16	4
F	0.125	0.07	1
G	0.45	0.26	6
H	0	0.06	1
I	0	0.02	0
J	0	0.03	1
6-PGDH: Slow	0.20	0.23	7

The left column shows the frequency of each rDNA type based on two samples of XO males and averaged over all OK. lines (see text). The second column gives the frequencies in the OK. mixed populations based on about three XO males sampled from each population and averaged over all 38 populations. The right column shows the number of OK. mixed populations in which the particular rDNA type was the only one found. The bottom row shows frequencies for the 6-phosphogluconate dehydrogenase (6-PGDH) slow allozyme. The average 6-PGDH allozyme frequencies for the OK. lines are taken from Downes[27]. The methods used for constructing XO males and for DNA extraction, restriction, transfer and hybridization are the same as described in Fig. 2 legend except that the DNA was fractionated on 0.8% agarose gels. The 6-PGDH allozyme carried by each XO male was determined by homogenizing the fly in a drop of water followed by electrophoresis of the extract in a 12.5% starch gel and staining the gel for 6-PGDH. The conditions used for electrophoresis and subsequent staining were as described by Downes[27].

lines suggests that the larger *Hae*III fragment lengths in these chromosomes are due to an increase in the number of 250 bp repeats.

Variations in NTS length that are due to fluctuations in the lengths of the fragment to the left of the *Alu*I region occur in OK. lines 2a and 9a, as both have a major fragment ~250 bp below the common 1.9 kb size (Fig. 3). This is also reflected in the *Hae*III digests which show a prominent band ~250 bp below the common 5.1 kb length (Fig. 2). As both the *Alu*I repetitive region and the *Alu*I fragment to the left of it lie entirely within the NTS, these results confirm that the length variation of the *Hae*III NTS fragment is due primarily to changes in the length of the NTS itself and not to changes in the 28S gene or ETS.

Variation in NTS length in rDNA clusters of the Y chromosome

To analyse the rDNA variation between individual Y chromosomes, males from the OK. lines were mated to C(1)DX/Y females. The C(1)DX/Y progeny contain rDNA mainly from the Y chromosome because the C(1)DX chromosome contains no detectable amounts of rDNA[20]. *Hae*III digests of DNA from C(1)DX/Y females containing Y chromosomes, sampled in 1979, from eight of the OK. lines were probed with the NTS clone and revealed 10 different rDNA patterns (Fig. 4).

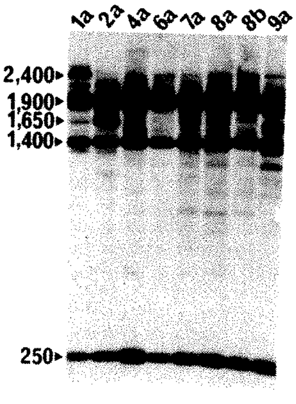

Fig. 3 Autoradiographs of total DNA of XO males after digestion with *Alu*I and hybridization to ^{32}P-labelled NTS clone pDm103HH2. Each track contains the DNA of four XO male progeny from a cross between an OK. male and an XX/O female (see Fig. 2 legend for details). The source of the OK. male parent is indicated above each track. In each case DNA was extracted from the same XO male progeny as used in the corresponding track of Fig. 2. Arrows on the left indicate fragment sizes in base pairs. *Alu*I digests were in 6 mM Tris-HCl *p*H 7.6, 6 mM $MgCl_2$, 1 mM dithiothreitol and DNA was electrophoresed in a 2% agarose gel. The methods used for DNA extraction, transfer and hybridization are the same as described in Fig. 2 legend.

The internal repetitive structure of Y chromosome NTSs from five different OK. sublines was investigated using *Alu*I and the NTS probe (data not shown). As with the X chromosomes, major bands are seen at 250 bp and 1.4 kb. However, the 1.9 kb band, corresponding to the fragment left of the *Alu*I region in X chromosomes (Fig. 1), is not prominent in any subline. Instead, a new major band is revealed at either 1.2 or 1.65 kb. A greater similarity between different Y chromosomes than between Y and X chromosomes, as found for the organization of rDNA repeats, has been found for other rDNA characteristics[21,22] and may be a result of the genetic isolation of the NOs on the X and Y chromosomes. Interestingly, the isolation has been sufficient for a particular character (the presence or absence of the 1.9 kb band in this case) to spread to a high proportion of the rDNA repeats of the NO.

High correlations for rDNA patterns between sublines separated for over 200 generations

By comparing the different X chromosome *Hae*III patterns in the OK. lines it is possible to classify them into seven types—A to G (Fig. 2). For 8 of the 10 cases, the rDNA patterns of the chromosomes sampled are indistinguishable between the a and b sublines, showing that the variation between lines is due to a polymorphism in the original Oklahoma population. When the XO male progeny derived from a different set of OK. line XY males were analysed, the same patterns as before were obtained, except for OK. lines 1a, which had pattern D, and 2b, which had pattern B. The a/b correlation in this sample of chromosomes is, however, the same as before, as sublines 2a and 2b are identical and 1a and 1b different.

Similarly, 10 Y chromosome rDNA patterns can be classified (M to W; Fig. 4). In four cases the a and b sublines are identical and in OK. line 5 they differed by only one band, possibly due to slight partial digestion. That differences between a pair of a and b sublines may be due to double insemination of the ancestral Oklahoma females leading to the introduction of two Y chromosomes in the subsequent progeny is consistent with an estimated frequency of ~50% for double insemination in a wild population of *D. melanogaster*[23]. An alternative explanation is that the a/b differences are due to variation generated during the 9 yr of laboratory maintenance.

Discontinuous variation of NTS length and copy number

One of the most striking features of the NTS length variation is that, despite the large fluctuations in copy number of many of the different lengths of NTS, a prominent 5.1 kb *Hae*III NTS length is common to most of the X and Y chromosomes (Figs 2, 4), which may reflect either a preference for this length by the mechanism producing the variation or its conservation due to natural selection. NTS length is usually confined to between 3 and 6 kb in the *D. melanogaster* sibling species subgroup[12] and *D. hydei*[24], *D. virilis*[25] and other Dipterans (such as *Calliphora erythrocephala*[26]).

An interesting feature of the NTS length variation is the differential abundance of many of the NTS lengths other than 5.1 kb. For example, the 9.6 kb *Hae*III NTS fragment of the X chromosome of OK. line 1 represents ~10% of the total repeats (estimated by microdensitometry and accounting for length), but no more than 1.5% in other X chromosomes from the Oklahoma stocks (Fig. 2). Assuming there are 250 copies of the rDNA repeats on the X chromosomes, these percentages represent 25 and 4 repeats respectively. Thus repeats in an array do not evolve independently, rather variants somehow spread in the array.

What mechanism might underlie the latter process? The data can be explained by unequal exchange occurring at two different levels. First, unequal staggers at the level of the region of repetition in the NTS (see Fig. 1) would generate NTS length heterogeneity. Second, unequal staggers at the level of the total rDNA units would generate the differences in copy number of each NTS length.

Continual unequal exchange at these two levels would contribute to the amplification or elimination of one or other of the rDNA lengths and hence explain the observed discontinuities in copy number of lengths. In addition, a continual turnover of rDNA by unequal exchange could explain the homogeneity within a species for variant sequences in regions of rDNA, that is, concerted evolution[1,12] (see below). Homogenization of a rDNA variant facilitates the expediency with which natural selection accepts or rejects, if need be, the variant in question. It is improbable that a single variant member of a multigene family of 400 members would have sufficient effect on the phenotype to be recognized by natural selection. However, a mechanism which amplifies or reduces the copy number of a variant to different degrees on different chromosomes will increase its contribution to phenotypic variance and hence the effectiveness with which natural selection may act on it.

Behaviour of rDNA types in mixed laboratory populations

To investigate the important question of the degree to which natural selection may be acting on the variation at the rDNA locus, we analysed populations derived from mixtures of flies from the OK. lines. In 1974 10 replicate populations were set up, each with 10 males and 10 females from each of the 20 OK. sublines, 1a–10b. After the first generation each population was divided into four sub-populations, each of which was subsequently maintained on fly medium containing a different species of yeast as food. After 6 yr (~150 generations) several males were sampled from 38 of these 40 OK. mixed populations and mated to $\hat{X}X/O$ females to produce XO male progeny. Restriction enzyme analysis of the XO male DNA with *Hae*III and probing with the NTS clone showed that all the original rDNA types found in OK. lines 1–10 were also present in the OK. mixed populations and that, in addition, three new types of rDNA pattern could be identified (H, I, J in Fig. 5). At least two (usually three) X chromosomes were analysed from each population and classified.

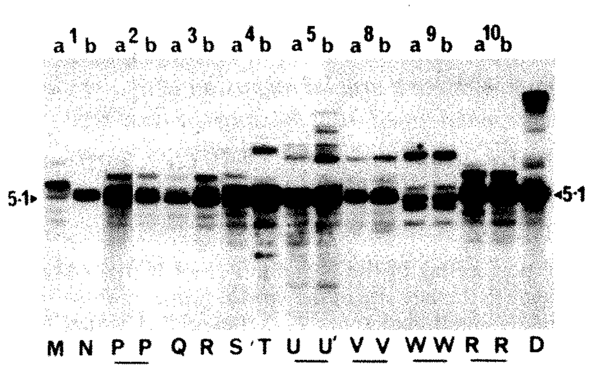

Fig. 4 Autoradiographs of total DNA of individual $\hat{X}X_{-NO}/Y$ males after digestion with *Hae*III and hybridization to ^{32}P-labelled NTS clone pDm103HH2. Y chromosomes were derived from males sampled from the sublines of OK. lines 1–5, 8–10 in 1980. The various hybridization patterns have been classified into 10 types (M–W). Subline 5b has been labelled U' because it differs by only one minor band from 5a (see text). Those lines in which the sublines show similar patterns are underlined. The rightmost track is an OK. mixed XO male with pattern D (see Fig. 5) run on the same gel for comparison. Arrows indicate sizes of fragments in kilobases. The $\hat{X}X_{-NO}/Y$ females were constructed by mating an OK. male with females from a mal/C(1)DX, y f stock. Progeny were checked to ensure that all females had a yellow and all males a wild-type body colour. Yellow females were collected and stored frozen at −70 °C for up to 6 months. The methods used for DNA extraction, restriction, transfer and hybridization are the same as for Fig. 2 except that a 0.8% agarose gel was used.

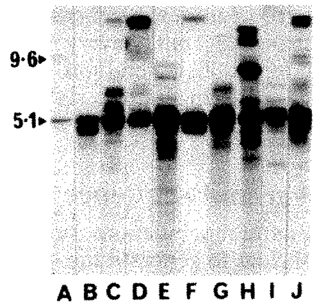

Fig. 5 Autoradiographs of total DNA of XO males after digestion with *Hae*III and hybridization to ^{32}P-labelled NTS clone pDm103HH2. Each track contains the DNA of four XO male progeny from a cross between an OK. mixed male and an $\hat{X}X/O$ female (see Fig. 2 legend for details). Tracks have been chosen to represent all the types of rDNA pattern found in the OK. mixed lines investigated. Types A–G are the same as those found in the OK. lines (Fig. 2) and three new types, H, I and J, are shown. Arrows on the left indicate fragment sizes in kilobases. The methods used for DNA extraction, restriction, transfer and hybridization are the same as for Fig. 2 except that the DNA was fractionated on 0.8% agarose gels.

The frequencies of the rDNA patterns showed no statistically significant correlation with any yeast species; thus the populations may be treated as 38 replicates. The frequency of each rDNA type, averaged over all 38 populations, was not significantly different from its frequency in the OK. lines, indicating that there has been no strong selection in these conditions for or against any particular type of rDNA (Table 1). However, there might be strong selection in each population maintaining the original rDNA type frequencies. On this basis, it might be expected that the frequencies in each population would show some resistance to genetic drift and remain relatively unaltered. That 27 out of 38 populations contained only one rDNA type, detected in average sample sizes of three, clearly shows the final populations are more homogeneous than expected from the overall initial frequencies, probably due to genetic drift. This conclusion is supported by studies[27] on autosomal allozyme frequencies of the same mixed populations which indicate an average population size of ~90–400. Additionally, the XO males used for the rDNA analysis have been assayed for the X-linked allozyme variant 6-phosphogluconate dehydrogenase which is 65 map units away from *bobbed*[28]. The degree of 'fixation' of this variant in the populations is similar to that of rDNA type G which has a comparable overall frequency calculated from all the populations combined (Table 1). Thus both the overall frequencies and the frequencies within populations indicate that there has been no strong selection of rDNA variants in these circumstances.

Stability of rDNA types in the laboratory

The data from the separate OK. lines and the OK. mixed populations show that the rDNA types of the X chromosomes have been stable in the laboratory. In the OK. lines no rDNA pattern has been found which is restricted to only one subline when all X chromosome replicate samples are taken into account. As at the time of analysis each a/b subline had been separate for over 200 generations, then the probability that a pattern remained unchanged in both sublines is $(1-m)^{400}$, where m is the rate of detectable change per generation. The probability that no unique type would be sampled in any of the 10 pairs of lines is therefore $(1-m)^{4,000}$. If m were $\frac{1}{1,250}$, this would give a probability of 0.05. The data therefore suggest that the rate of detectable change in the laboratory is <1 in 1,250 generations.

Analysis of the OK. mixed populations revealed only three rDNA types not found in the OK. lines. One of these, H, is present in more than one population and could have been present when the OK. mixed populations were established. The other two types, I and J, could either be newly generated variants, or were left undetected in the OK. lines. If we assume that these types have been newly generated, then this would indicate a rate of change of 2 out of every 38 populations in 150 generations, or 1 in 3,000 generations. Such estimates are consistent with rates of change at the rDNA locus of 3×10^{-4} estimated by analysis of bristle selection lines[29].

Family turnover and sequence fixation

When considering natural populations, such mutation rates are quite high and sufficient to generate the very extensive rDNA polymorphism observed in effective population sizes of 10^4–10^5 with no selection. If the high polymorphism is indeed a result of a high rate of unequal exchange which can amplify or reduce the copy number of variant repeats, then on an evolutionary time scale the rDNA family would be in a continual state of turnover. The rate of turnover would influence the extent to which an array becomes homogeneous for a variant rDNA unit[4]; and the breeding size of a population would influence the extent to which a variant array becomes fixed in a population[5]. Natural selection would interact with these processes depending on the variant in question.

Our calculations, however, of the extent to which the above assessments of the rate of turnover and stability of rDNA types can explain the concerted evolution of rDNA sequence variants in the *melanogaster* subgroup suggest that additional forces might be necessary to drive specific variants to fixation[1,12]. Observations that continual homogenization is occurring in families on different sex chromosomes (such as the rDNA arrays) or on many different chromosomes[8,30,31] suggest that mechanisms of non-reciprocal interchromosome transfer and 'conversion' of sequences are involved with fixation[1,3,8]. We discuss elsewhere[1] the extent and significance of such a process of molecular drive in the evolution of multigene families.

Activation of SV40 genome by 72-base pair tandem repeats of Moloney sarcoma virus

Barbara Levinson, George Khoury, George Vande Woude & Peter Gruss

Laboratory of Molecular Virology, National Cancer Institute, National Institutes of Health, Bethesda, Maryland 20205, USA

The simian virus 40 (SV40) 72-base pair (bp) tandem-repeated sequences have a crucial role as an activator element in viral gene expression. We replaced the SV40 72-bp repeat with a 72-bp repeat derived from the long terminal repeat (LTR) of cloned Moloney murine sarcoma virus (MSV) DNA. Although there is no detectable sequence homology to SV40, the MSV repeats can substitute functionally for the SV40 repeats and generate a viable virus in monkey kidney cells.

THE identification of nucleotide signals directing the initiation of transcription should provide an insight into the complex regulatory mechanisms controlling the activity of eukaryotic genes. In this regard, the DNA tumour viruses such as SV40 probably represent the best studied model systems. Experimental approaches using SV40 have been facilitated by the detailed information available concerning viral genetics, together with a knowledge of the entire nucleotide sequence of the small circular genome and the 5′ termini of the mRNAs (see ref. 1 for review).

Various control elements have been localized to the region around the origin of SV40 DNA replication. Besides binding sites for the multifunctional early gene product, the large T-antigen[2–6], a Goldberg–Hogness (G–H) box precedes the most abundant early mRNA cap sites by ~25 nucleotides[7,8]. Recent data[9–12] suggest that the G–H box is dispensable for *in vivo* expression of the SV40 early genes but is apparently involved in precise positioning of the 5′ termini of early mRNAs. Further upstream (to the late site of the viral genome) are several sets of tandem-repeated sequences[7,8,13], the role of which has been investigated by constructing deletion mutants. Although little is known about the function of the 21-bp repeat, several sets of mutants have focused on the function of the 72-bp tandem repeat. Removal of precisely one 72-bp repeat does not affect viability of the viral genome[13–16], but if the deletion is extended into the second 72-bp repeat, the genome becomes nonviable[16]. Similar conclusions have been drawn from parallel experiments using constructed plasmids[10]. On the basis of these data, we concluded that the 72-bp repeat is essential for the expression of the early SV40 genes.

Several other viral systems have elements which bear a structural resemblance to the 72-bp repeat and possibly express related activities[16,17]. Although no significant sequence homology to the SV40 72-bp repeat has been detected[17,18],

0028-0836/82/070568—05$01.00

studies on the LTRs of cloned MSV revealed putative transcriptional control elements and a 72-bp tandem repeat preceding by ~180 nucleotides the 5′ end of all the major mRNAs[18]. Furthermore, it was demonstrated in DNA transfection–transformation assays that the viral LTR provides all the necessary functions for activation of transforming genes[19–21], including the SV40 T-antigen (M. Krigler and M. Botchan, and M. McGeady *et al.*, personal communications).

Based on these observations, we decided to investigate the possibility that other sequences from nonhomologous sources (like MSV) might replace the functional activity of the SV40 repeats, and whether tandem-repeated elements might be involved in host range. Here we demonstrate that although the nucleotide sequence of the MSV 72-bp repeat differs from that of SV40, it has similar functional activity and can rescue the *cis*-defective SV40 deletion mutant, thus generating a viable recombinant virus. This recombinant virus can express early SV40 genes in monkey kidney cells and in mouse cells.

Construction of the recombinant

The construction of the SV40 recombinant carrying the 72-bp tandem repeat from MSV is illustrated in Fig. 1. In the protocol used, we first cloned a recombinant plasmid harbouring the entire SV40 genome except for the 72-bp tandem repeats. For this purpose, we removed from the DNA of a viable SV40 variant bearing a second *Bam*HI site, the *Sph*I–*Bam*HI region (218 bp) comprising almost all nucleotide sequences from both 72-bp repeats plus some flanking sequences from the end of the repeat to the *Bam*HI site (nucleotide 348 (ref. 13), the former *Hpa*II site). A pBR322 derivative (pA10) was constructed which contained a short stretch of nucleotides with the *Eco*RI, *Xba*I and *Bam*HI restriction enzyme sites. The pA10 plasmid was cleaved with *Sph*I and *Bam*HI and the larger fragment was ligated to the *Sph*I–*Bam*HI SV40 fragment lacking the two 72-bp repeats. This cloned recombinant plasmid pSV-r$^-$ served as the recipient for the insertion of the 72-bp repeats from the LTR of cloned Moloney murine sarcoma viral DNA. A convenient 199-bp fragment containing primarily the two 72-bp MSV repeats was generated using *Xba*I and *Sau*3A (an isoschizomer of *Mbo*I which cleaves G$^{\text{Me}}$ATC as well as GATC). For ligation, the plasmid recipient pSV-r$^-$ was partially cleaved with *Bam*HI to generate mainly single-cut linear molecules and the purified linear molecules were cleaved to completion with *Xba*I. The large fragment was ligated to the *Sau*3A–*Xba*I fragment derived from the MSV LTR (*Bam*HI and *Sau*3A have identical cohesive ends). Polar insertion of the MSV repeat was achieved because both fragments contained two non-identical termini. The polarity of the MSV repeat in the recombinant was the same as that of the 72-bp repeat in the SV40 wild-type (wt) genome. After cloning of this plasmid (pSV-r$^{\text{MSV}}$) in *Escherichia coli* HB101, the viral sequences were separated from the plasmid sequences by cleavage with *Sph*I and *Xba*I (see Fig. 1).

Biological activity of SV-r$^{\text{MSV}}$

To assay the functional activity of the MSV 72-bp repeat, we transfected the linear SV40–MSV recombinant (SV-r$^{\text{MSV}}$) into African green monkey kidney (AGMK) cells using DEAE-dextran as a facilitating agent. As a control, the *Xba*I–*Sph*I linear molecules that did not contain the MSV 72-bp repeats (SV-r$^-$) were transfected in parallel. After ~10 days, a SV40 cytopathic effect (CPE) was seen on dishes transfected with SV-r$^{\text{MSV}}$ DNA, whereas no vacuolization was seen in control plates. Sixteen to eighteen days after transfection, the cells which received SV-r$^{\text{MSV}}$ DNA were completely lysed, whereas there was no CPE apparent on the control plates. To demonstrate infectious virus, the lysate was filtered through a nitrocellulose filter (Millipore, 0.45 μm pore size) and subsequently used to reinfect AGMK cells; CPE was observed 3–4 days after infection and complete cell lysis occurred after ~7–10 days. No CPE was observed on the control plates infected with SV-r$^-$ lacking the MSV repeats.

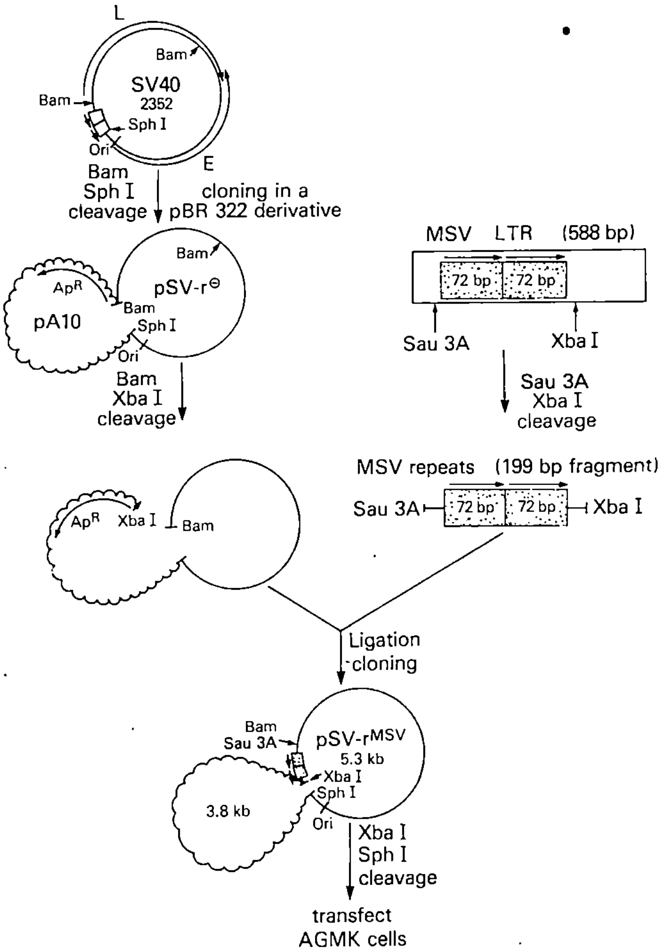

Fig. 1 Construction of SV-r$^{\text{MSV}}$ recombinants. A viable variant of SV40 (2352) carrying a second *Bam*HI site at the *Hpa*II site (P.G., unpublished results) was partially cleaved with *Bam*HI and unit-length molecules isolated after electrophoresis in 1.4% agarose gels[33]. These linear molecules were cleaved to completion with *Sph*I to remove a fragment (218 bp) constituting the majority of the SV40 72-bp repeats (plus sequences from the end of the repeat to the *Bam*HI–*Hpa*II site). This SV40 repeat-minus deletion mutant (SV-r$^-$) resembling our recently reported *cis*-defective SV40 deletion mutant 2356 (ref. 16), was cloned in a pBR322 derivative (pA10). pA10 differs from pBR322 (ref. 34) primarily in the presence of a polylinker *Eco*RI, *Xba*I and *Bam*HI. In addition, it carries a deletion in the tetracycline-resistance (Tc$^{\text{r}}$) gene (from *Eco*RI to *Bam*HI). This was achieved by deletion of the small *Eco*RI–*Bam*HI fragment from pBR322. Subsequently, the protruding 5′ ends of the remaining larger fragment were filled using T4 polymerase[35], and *Xba*I linkers were ligated to the blunt ends. The pA10 plasmid was restricted with *Bam*HI and *Sph*I and the larger fragment isolated by electrophoresis in a 1.4% agarose gel. This fragment was ligated[33] to the *Bam*HI, *Sph*I-cleaved SV40 DNA fragment and cloned in *E. coli* HB101[36,37]. After isolation[38,39], the superhelical recombinant plasmid DNA (pSV-r$^-$) was partially cleaved with *Bam*HI and the unit-length recombinant plasmid purified by agarose gel electrophoresis. The linear pSV-r$^-$ DNA was subsequently cleaved to completion with *Xba*I and the large fragment again purified by agarose gel electrophoresis. In parallel, the recombinant plasmid carrying the cloned MSV LTR sequences[21] was cleaved with *Sau*3A and *Xba*I and a 199-bp fragment isolated by polyacrylamide gel electrophoresis[33]. This fragment was ligated to the pSV-r$^-$ plasmid and cloned in *E. coli* HB 101[36,37]. Cloned plasmids were identified by restriction enzyme analysis using *Xba*I and *Eco*RI followed by blotting[22], then hybridized with ^{32}P-labelled MSV LTR DNA probe. Only the predicted fragment had homology to this probe. One of the recombinants carrying the MSV 72-bp repeats, pSV-r$^{\text{MSV}}$, was subsequently cleaved to completion with *Xba*I and *Sph*I, releasing the viral recombinant from the plasmid sequences, and 5 μg of DNA transfected on to 1×10^6 secondary AGMK cells using DEAE-dextran as facilitating agent[16]. As a control, 5 μg of the plasmid pSV-r$^-$DNA, cleaved with *Xba*I and *Sph*I, was similarly transfected.

Analysis of SV-r$^{\text{MSV}}$ recombinant DNA

Having tentatively established the presence of an infectious virus in the cell lysate, we then had to characterize the structure of the recombinant viral DNA molecules. AGMK cells were inoculated in parallel with wild-type SV40 or the SV-r$^{\text{MSV}}$ virus stock. Superhelical DNA was isolated from infected cells

Fig. 2 DNA sequence analysis of the SV-r^{MSV} recombinant. Ten flasks (150 cm^2) of secondary AGMK cells were infected with 1 ml each of SV-r^{MSV} and superhelical viral DNA was collected 4 days after infection[40]. The viral DNA (20 μg) was cleaved to completion with *Mbo*I and the enzyme removed by phenol extraction. DNA fragments were terminally labelled with [γ-^{32}P]ATP[24] and separated in a 4% polyacrylamide gel[31]. A fragment of 844 bp was isolated, the DNA was electroeluted and re-cleaved with *Bgl*I. The smaller fragment (307 bp) was purified by 4% acrylamide gel electrophoresis and sequenced using the forward-backward method[25]. Nucleotides read from the 6% polyacrylamide-urea gel are underlined; the others were deduced from the construction (see Fig. 1) and from the published sequences of SV40[7,8,13] and MSV[18].

labelled with ^{32}P. To test for the presence of MSV sequences in the recombinant virus, we hybridized the labelled DNA to a Southern blot[22] containing a DNA fragment from the cloned MSV LTR[23]. Only SV-r^{MSV} DNA, and not control SV40 wt DNA showed homology to the MSV LTR sequences (data not shown). Furthermore, the restriction enzyme pattern of SV-r^{MSV} DNA followed exactly the predicted structure. The presence of the acquired *Sau*3A (*Mbo*I) site used for ligation (see Fig. 1), and *Pvu*II sites present in each MSV 72-bp repeat, further clarifies the physical structure of SV-r^{MSV} recombinants. As expected, the *Sph*I site present in the SV40 72-bp repeat was missing (Fig. 2).

As linear molecules were used for the initial transfection of AGMK cells, it is likely that during circularization by cellular enzymes, several nucleotides were removed from each terminus. To determine more precisely the structure of the recombinant, we analysed the nucleotide sequence in the region encompassing the junction between SV40 and MSV sequences. An *Mbo*I fragment (844 bp) containing the entire MSV insert joined to SV40 sequences around the origin of replication was isolated, terminally labelled[24], re-cleaved with *Bgl*I and the smaller fragment (307 bp) purified by gel electropohoresis. A recently described dideoxy sequencing method was used[25]; the physical structure and nucleotide sequence around the recombinant junction are outlined in Fig. 2. Both MSV repeats were found to be present. As deduced from the restriction enzyme analysis, 22 nucleotides precede the first repeat. Although the SV-r^{MSV} linear molecule used for infection of AGMK cells had ~36 bp flanking the terminus of the second repeat, 20 nucleotides (including the terminal *Xba*I site) were deleted, presumably through the action of cellular nucleases. This left 14 nucleotides of MSV sequence after the second repeat and before the SV40 junction (atgcggtÇATCTCA·). Three nucleotides were deleted from the SV40 sequence, including those of the *Sph*I site (the Ç at the junction may derive either from MSV or SV40). As very few nucleotides were deleted from SV40, both SV40 21-bp repeats were preserved. The third binding site for T-antigen, which has been localized to the 21-bp repeats[26], was also present in the recombinant virus.

Analysis of mRNAs transcribed from SV-r^{MSV} recombinants

To analyse the mRNAs transcribed from the recombinant genome, AGMK cells were infected in parallel with either wt SV40 or the SV-r^{MSV} recombinant. Poly(A)-containing cytoplasmic RNA was isolated and analysed by the nuclease S$_1$ technique[27,28]. Using an SV40 DNA probe uniformly labelled *in vivo*, both early and late transcripts were detected in cells infected with SV-r^{MSV} recombinant virus (Fig. 3*a*). No difference was observed in the spliced bodies compared with SV40 early or late (19S, 16S) mRNA. As SV-r^{MSV} recombinants do not retain the nucleotide sequences coding for the 5′ ends of the most abundant late transcripts, it was of interest to investigate further the structure of the late mRNAs. For this analysis, we used a uniformly labelled *Hpa*II–*Bam*HI fragment B. The results (Fig. 3*b*) indicate that the 5′ ends of the SV-r^{MSV} late transcripts are located further upstream towards the origin of replication than the *Hpa*II end of the DNA probe. This suggests the presence of novel 5′ ends located probably in MSV sequences. The 5′ termini of the early mRNAs seem identical to those of wt SV40 (data not shown).

Protein induced by the SV-r^{MSV} recombinants

As the overall structure of early and late mRNAs of SV-r^{MSV} were very similar to transcripts of SV40 wt RNA, it seemed likely that the translational products also would be similar. To confirm this, AGMK cells were infected in parallel with wt SV40 virus or the SV-r^{MSV} recombinant stock. About 72 h after infection, cells were labelled with ^{35}S-methionine for 2 h. Proteins were extracted and immunoprecipitated either with a hamster antiserum recognizing both the early T-antigen and late VP-1 capsid protein or with normal hamster antiserum, then analysed by gel electrophoresis (Fig. 4). Both T-antigen and

VP-1 co-migrate with the SV40 wt markers. These data establish the physical integrity and functional activity of SV-r$^{\rm MSV}$ recombinants.

Conclusion

In previous studies[10,16] we and others have defined sets of repeated sequences to the late side of the SV40 replication origin as being essential for the transcription of viral gene sequences. Unlike the so-called Goldberg–Hogness sequence, which seems to be responsible for setting the 5′ end of eukaryotic transcripts[9-12], these repeated sequences appear to contribute to the transcriptional activity of genes located in their general vicinity. Thus, we designated them 'activator' elements. Presumably these SV40 activator elements enhance the expression of heterologous genes introduced into eukaryotic cells in a variety of cDNA transfection experiments (ref. 29 and V. B. Reddy and W. Schaffner, personal communications). Studies are now being directed at determining what part the position and orientation of such sequences play in contributing to gene activity.

At first glance, the striking feature of the SV40 activator element is its repetitive nature, although one copy is sufficient for its functional activity[13-16]. In searching for similar sequences among other eukaryotic genes and viral genomes, we focused on the 72-bp repeats in the MSV LTR. The position of the repeat within the LTR (a set of ~600 nucleotides which had previously been shown capable of restoring transforming activity to viral and cellular sarcoma virus genes[19-21]) indicated that it might have an analogous role in the regulation of retrovirus gene activity. The MSV 72-bp repeat sequence was therefore used to demonstrate similar functional activity by reactivating an SV40 deletion mutant lacking the SV40 72-bp repeats. As mentioned above and elsewhere[17,18], this heterologous set of nucleotides bears little if any resemblance to the original SV40 sequence. Restriction endonuclease analysis and DNA sequencing methodology has established the physical structure of a recombinant virus which retains the SV40 21-bp repeat elements and carries a 167-bp insert, most of which represents the MSV 72-bp repeats. This recombinant virus induced the synthesis of polypeptides indistinguishable from those of wt SV40. The structures of the viral RNAs were similar to those of SV40, except for the 5′ ends of late mRNAs, most of which probably reside in the acquired MSV sequences. This result is expected as the nucleotide sequence encoding the most common 5′ ends of late SV40 mRNAs has been deleted from the SV-r$^{\rm MSV}$ recombinants. In addition, alterations representing either deletion mutants[30] or recombinant viral genomes[31] in this region of SV40 frequently generate novel 5′ termini of the late SV40 mRNA species. That the activator function of the mutant virus resides in the MSV 72-bp sequences and is not simply dependent on a 'spacer' function has been demonstrated in part by previous experiments. Studies in which plasmid sequences were substituted for the SV40 72-bp repeats (ref. 10 and our unpublished results) did not lead to the activation of early SV40 functions.

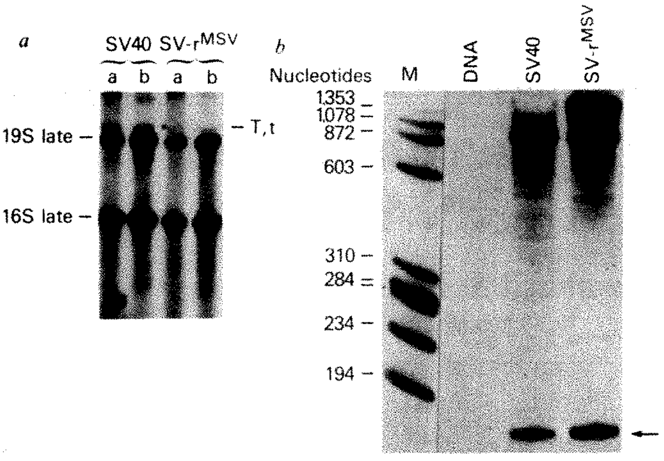

Fig. 3 Analysis of SV-r$^{\rm MSV}$ RNA. Cytoplasmic poly(A)-containing RNA was isolated[41] 72 h after infection of secondary AGMK cells with SV-r$^{\rm MSV}$ and SV40 wt viral stock. The RNA was analysed using the nuclease S$_1$ procedure[27,28]. *In vivo* ^{32}P-labelled SV40 wt DNA (specific activity 1×10^6 c.p.m. per μg DNA) was used as probe. *a*, S$_1$ analysis in a 1.4% alkaline agarose gel of SV-r$^{\rm MSV}$ RNA and control SV40 RNA annealed with the uniformly labelled SV40 wt DNA, linearized at the *Hpa*II site. RNA was prepared from 6×10^6 cells (a) or 2.5×10^7 cells (b) infected with SV-r$^{\rm MSV}$ from 1×10^6 (a) or 6×10^6 cells (b) infected with wt SV40. *b*, Analysis of SV-r$^{\rm MSV}$ RNA (from. 2.5×10^7 cells), SV40 wt RNA (from 1×10^6 cells) and no RNA (DNA control) in an 8% polyacrylamide-urea gel[24]. In this experiment, SV40 wt *Hpa*II–*Bam*HI fragment B was used as a probe representing the late region of the genome. M represents terminally labelled fragments of ΦX 174 DNA.

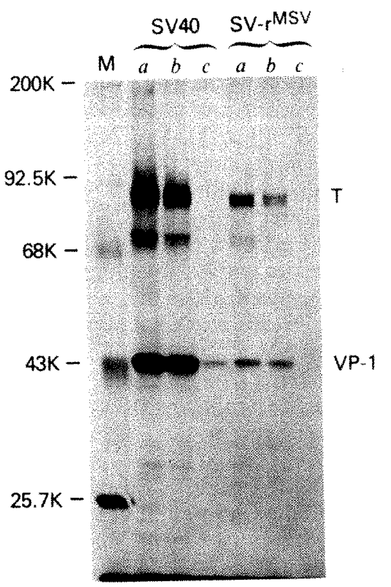

Fig. 4 Analysis of SV-r$^{\rm MSV}$ proteins. One flask of secondary AGMK cells (2×10^7 cells) was infected with 1 ml of either SV-r$^{\rm MSV}$ or wt SV40 (control). At 40 h post-infection, each culture was starved for 1 h in methionine-free medium and labelled for 2 h with ^{35}S-methionine (35 μCi ml^{-1}) in methionine-free medium. Viral proteins were extracted by treating the cells with 2 ml each of lysis buffer (0.01 M Tris *p*H 8.1, 0.1 M NaCl, 0.1% NP-40, 1 mM dithiothreitol, 2mM phenylmethylsulphonyl fluoride, 100 μg ml^{-1} tosylphenylethylchloromethylketone). The insoluble fraction was removed by centrifugation in a Beckman 50TI rotor at 40,000 r.p.m. for 30 min. Viral proteins were immunoprecipitated[42,43] with a hamster antiserum recognizing both tumour(T)-antigen-specific and protein (VP-1)-specific imunodeterminants (*a*, *b*) or with normal hamster serum (*c*). The SDS/polyacrylamide gel system used was that of Laemmli[44]. Radiolabelled protein bands on the gel were detected by fluorography[45]. *a*, Protein extract from 3.75×10^6 cells; *b*, protein from 1.25×10^6 cells. K represents a molecular weight of 1,000.

Given a lack of sequence homology between the 72-bp repeats of SV40 and MSV, it is remarkable that the recombinant virus is viable. If these so-called activator elements are required to interact with a well defined set of host cell macromolecules (for example, proteins or nucleic acids), it is conceivable that they bear a nucleotide sequence homology to one another that is difficult to recognize. Perhaps this homology resides in an interrupted or irregularly distributed pattern of the critical nucleotides. In this respect, we have also considered the possibility that the repeat unit might form a secondary or tertiary structure which is important for its biological function. We found that the SV40, BKV and MSV repeat units can form extensive stem and loop structures (unpublished observations). Alternatively, it is possible that a number of unrelated sequences can provide a similar activating function in host cells by performing parallel functions with an analogous set of host macromolecules. BKV, a human papovavirus, contains three copies of a 68-bp sequence to the late side of its replication origin[32]. This putative activator, which functions in both human and AGMK cells, has no obvious nucleotide sequence homology to the activators of SV40 or MSV. In fact, the late repeated sequences represent the region of the papovavirus BKV genome that has the least sequence homology to SV40[13,17,32].

As we have suggested previously[16,17], activator sequences may have been acquired from host cellular DNA. If this is the case, one might speculate that such sequences could in some way influence the host range of viruses. In this regard, it is of interest that we were unable to detect normal plaques after inoculation of AGMK cells with SV-r^{MSV}, although minute plaques may have been overlooked. One possible explanation for the reduced growth of the recombinant virus on monkey cells is the absence of sequences between the second SV40 72-bp repeat and the converted *Hpa*II (*Bam*HI) site (see Fig. 1). A number of SV40 mutants having deletions in this region grow slowly (J. Mertz, personal communication and our unpublished results). On the other hand, the MSV repeats may function at a lower level in AGMK cells than in mouse cells, which is suggested by preliminary studies comparing T-antigen synthesis in mouse and monkey cells infected with either SV40 or the SV-r^{MSV} recombinant genome.

It is clear that an insight into the role of sequence specificity in activator elements will require a broader understanding of the function of these sequences in activating transcription from specific promoters. It may be that these elements provide viral genomes with a competitive advantage for growth in eukaryotic cells. Nevertheless, we suggest that not only viral genes but eukaryotic genes are regulated by the presence of activator elements, and experiments to identify such sequences in cellular DNA are now in progress.

We thank Monika König and L. Greenbaum for technical assistance; G. Jay, D. Cosman, N. Rosenthal and T. Wood for helpful discussions; and D. Little for preparing the manuscript. These experiments were conducted in accordance with the NIH Guidelines for Recombinant DNA. Studies with the recombinant virus stock in eukaryotic cells were conducted at the P3 containment level.

Intracellular transport of microinjected 5S and small nuclear RNAs

Eddy M. De Robertis, Susanne Lienhard & Ruth F. Parisot
Biocenter, University of Basel, Klingelbergstrasse 70, 4056 Basel, Switzerland

The mechanism by which some RNAs are segregated in the cell nucleus was analysed by microinjecting ^{32}P-labelled total RNA from HeLa cells into the cytoplasm of Xenopus *oocytes. Small nuclear RNAs (U1, U2, U4, U5 and U6) migrated into the cell nucleus, where they became 30–60 fold more concentrated than in the cytoplasm. Other RNAs, such as tRNA and 7S RNA, remained in the cytoplasm, while 5S RNA became concentrated in the nucleolus. Studies with lupus erythematosus antibodies showed that the migrating RNAs become associated with oocyte RNA-binding proteins.*

SOME types of RNA are normally located in the nucleus of eukaryotic cells, including heterogeneous nuclear RNA (hnRNA)[1,2], small nuclear RNAs (sn RNAs)[3,4] and tRNA precursors. However the mechanism by which these molecules become segregated is unknown. We became interested in this problem when studies with cloned tRNA genes microinjected into the nucleus of frog oocytes showed that they are transcribed initially into precursor RNAs containing 5′-leader and 3′-trailer sequences[5–8] which do not leave the oocyte nucleus[7,8]. As tRNA precursors with very short extra sequences (of $\sim$5 nucleotides) at the termini are retained in the nucleus, it did not seem likely that the nuclear segregation could result simply from the precursor tRNAs being too bulky to traverse the pores in the nuclear envelope. An alternative possibility is that the precursor RNAs might bind to other intranuclear molecules (such as processing enzymes) which could block nuclear exit either because of size or because they might have an intrinsic affinity for the nucleus, as is known to be the case for many nuclear proteins (see below).

Although other models could explain why some RNAs are located in the nucleus, the binding hypothesis has the advantage that it can be tested using available techniques. Indeed, it

0028–0836/82/070572—06$01.00

predicts that if naked RNA of nuclear origin were injected into the cytoplasm it should be able to diffuse within the cell and eventually accumulate in the nucleus, provided that the nuclear membrane did not block the free diffusion of RNA. This experiment, reported here, was carried out with snRNAs because they provide a convenient source of stable RNAs of nuclear origin.

A large variety of nuclear proteins migrate and accumulate in the nucleus after microinjection into the cytoplasm of frog oocytes[9–13], amoebae[14] or cultured cells[15]. Transient precursors are not involved and thus mature nuclear proteins accumulate in the nucleus, which they normally must re-enter at each mitotic division. The mechanism of accumulation is not yet certain, but on the basis of experiments involving damage of the nuclear membrane[16,17] and saturation with competing proteins[18] it is thought that nuclear proteins may bind inside the nucleus to a non-diffusible nucleoplasmic component(s). If some of the proteins with nuclear affinity were also RNA-binding proteins, then this could provide a mechanism for the intracellular segregation of RNAs.

In the present study we injected labelled RNAs extracted from HeLa cells into the cytoplasm of frog oocytes. The results show that snRNAs migrate into the nucleus, that 5S RNA enters the nucleus and becomes localized in the nucleolus, and that other RNAs (tRNA, 7S RNA) remain in the cytoplasm. The migrating snRNAs bind to oocyte proteins after microinjection, as shown by studies with lupus erythematosus antibodies.

Cellular distribution of microinjected HeLa ^{32}P-RNAs

HeLa cells were chosen as the source of RNA for these experiments because their small RNAs are well characterized[19–21] and are known to be highly conserved throughout evolution. Figure 1, lane *a*, shows the electrophoretic pattern of total RNAs extracted from HeLa cells labelled for 18 h with ^{32}P-orthophosphate. Previous observations[19–21] (which we confirmed, data not shown), relevant to our subsequent experiments, are: (1) some RNAs—tRNAs and 7S RNA (which is complementary to the Alu family of repeated genes)[21]—are preferentially cytoplasmic; (2) other RNAs are preferentially nuclear (U1–U6 snRNAs); and (3) 5S RNA and 5.8S RNA, although preferentially cytoplasmic, are also present in the nuclear fraction after labelling for 18 h, presumably reflecting the time course of assembly of the large ribosomal subunit of which they are part.

Figure 1 shows the results of two experiments in which total HeLa ^{32}P-RNA was injected into the cytoplasm of *Xenopus* oocytes, which were then incubated for 18 h and subsequently manually separated into nucleus and cytoplasm. Most of the injected low-molecular-weight RNAs (lane *a*) are stable after microinjection into oocytes (lane *b*). (An unequal number of counts were loaded in lanes *a* and *b*, but other experiments have shown that the degradation of most small RNAs is negligible.) Exceptions are U3 snRNA (a nucleolar snRNA[3]), which is to a large extent specifically degraded in the oocyte cytoplasm (Fig. 1, lane *b*), and 5.8S, 18S and 28S RNAs (not shown) which seem to diminish in amount relative to other RNAs. Comparison of the labelled RNAs present in the cytoplasm (Fig. 1, lanes *c*, *e*) and in the nucleus (Fig. 1, lanes *d*, *f*) of injected oocytes shows that: (1) the tRNAs and the 7S transcript remain in the cytoplasm (their normal cellular location) as well as 5.8S RNA (which has a complex biogenesis); (2) U1 and U2 snRNAs become more concentrated in the nucleus, although a part still remains in the cytoplasm; and (3) 5S RNA, although predominantly cytoplasmic, also enters the nucleus (but clearly to a lesser degree than U1 or U2).

The microinjected U1 and U2 RNAs concentrate in the nucleus to a remarkable extent. As the nucleus is much smaller than the cytoplasm (about 20 times by volume, 10 times if one assumes that one-half of the cytoplasm is occupied by yolk platelets[18]), and one cytoplasm and one nucleus from individual oocytes were analysed in the lanes of Fig. 1, the amounts of U1 and U2 snRNAs present in the nuclei (lanes *d*, *f*) should be multiplied by a factor of 10–20 to visualize the difference in terms of concentration. Despite slight variations (compare lanes *c*, *d* with lanes *e*, *f* in Fig. 1), generally at least three times as

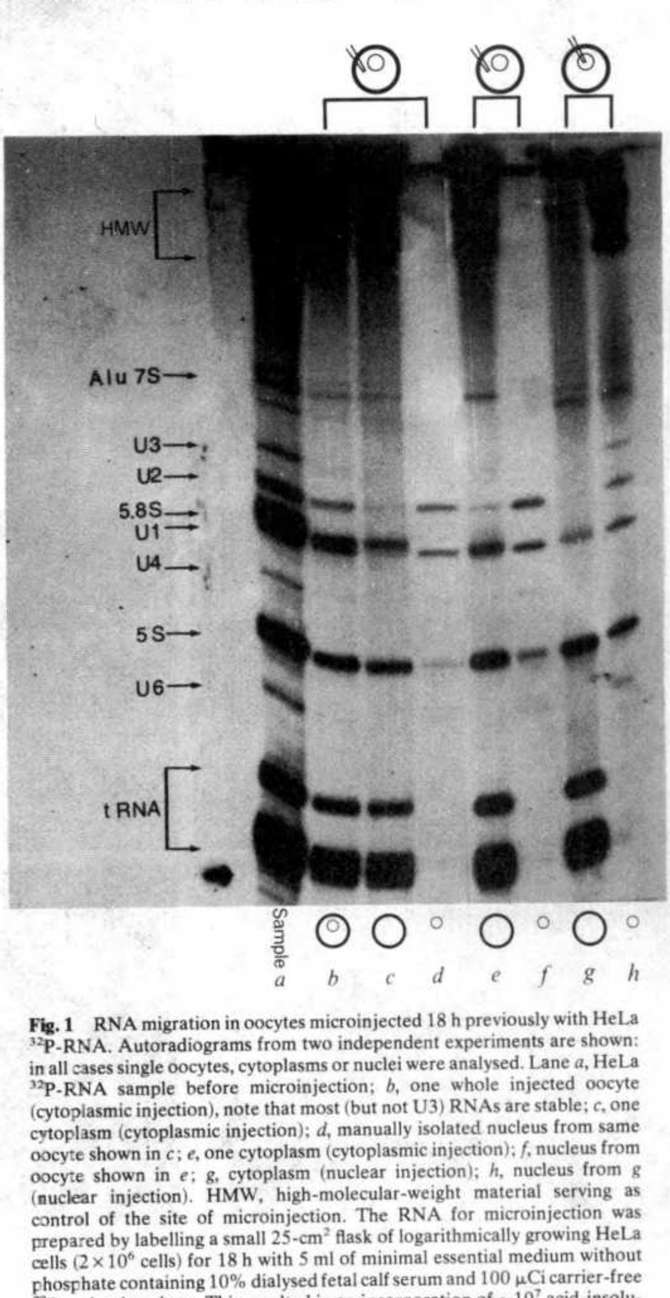

Fig. 1 RNA migration in oocytes microinjected 18 h previously with HeLa ^{32}P-RNA. Autoradiograms from two independent experiments are shown: in all cases single oocytes, cytoplasms or nuclei were analysed. Lane *a*, HeLa ^{32}P-RNA sample before microinjection; *b*, one whole injected oocyte (cytoplasmic injection), note that most (but not U3) RNAs are stable; *c*, one cytoplasm (cytoplasmic injection); *d*, manually isolated nucleus from same oocyte shown in *c*; *e*, one cytoplasm (cytoplasmic injection); *f*, nucleus from oocyte shown in *e*; *g*, cytoplasm (nuclear injection); *h*, nucleus from *g* (nuclear injection). HMW, high-molecular-weight material serving as control of the site of microinjection. The RNA for microinjection was prepared by labelling a small 25-cm^2 flask of logarithmically growing HeLa cells (2×10^6 cells) for 18 h with 5 ml of minimal essential medium without phosphate containing 10% dialysed fetal calf serum and 100 μCi carrier-free ^{32}P-orthophosphate. This resulted in an incorporation of $\sim10^7$ acid-insoluble c.p.m. per flask. Total nucleic acid was prepared by trypsinizing cells, washing in phosphate-buffered saline (PBS: 130 mM NaCl, 20 mM Na phosphate, *p*H 7.3), and lysing cells by vortexing in 1.5 ml of proteinase K–SDS solution (1.7% SDS, 300 mM NaCl, 2 mg ml^{-1} proteinase K, 40 mM Tris-HCl, *p*H 7.5). After phenol–chloroform extraction and addition of 2 vol of ethanol, the high-molecular-weight DNA was carefully spooled with a sealed 5 μl 'micropet' capillary (which very effectively reduces the viscosity thus allowing subsequent microinjection) and the remaining nucleic acids precipitated overnight at −20 °C, washed with 70% ethanol and the pellet finally redissolved in distilled water. Thirty nl of ^{32}P-RNA were injected into fully grown *Xenopus* oocytes and incubated overnight at 19 °C (ref. 39) before manual separation into nucleus and cytoplasm in J-buffer[40]. Samples were homogenized in proteinase K–SDS buffer, and the extracted nucleic acids[41] dissolved in 10 μl of loading buffer (95% formamide, 0.01% SDS containing Bromophenol blue and xylene cyanol) and electrophoresed in 8% polyacrylamide/7M urea thin (0.35 mm) 40 cm gels as previously described[5,6], except that 0.5X TBE buffer and faster runs (20 mA, electrophoresis completed in 1.75 h) were utilized. Each oocyte was injected with the RNA extracted from 500 HeLa cells. The cytoplasmic injection experiment shown here is highly reproducible, and was repeated in more than 10 independent experiments using oocytes from different frogs. It was also carried out successfully by the undergraduate biology students of the Biocenter in a practical course, showing that the manipulations involved are not excessively difficult.

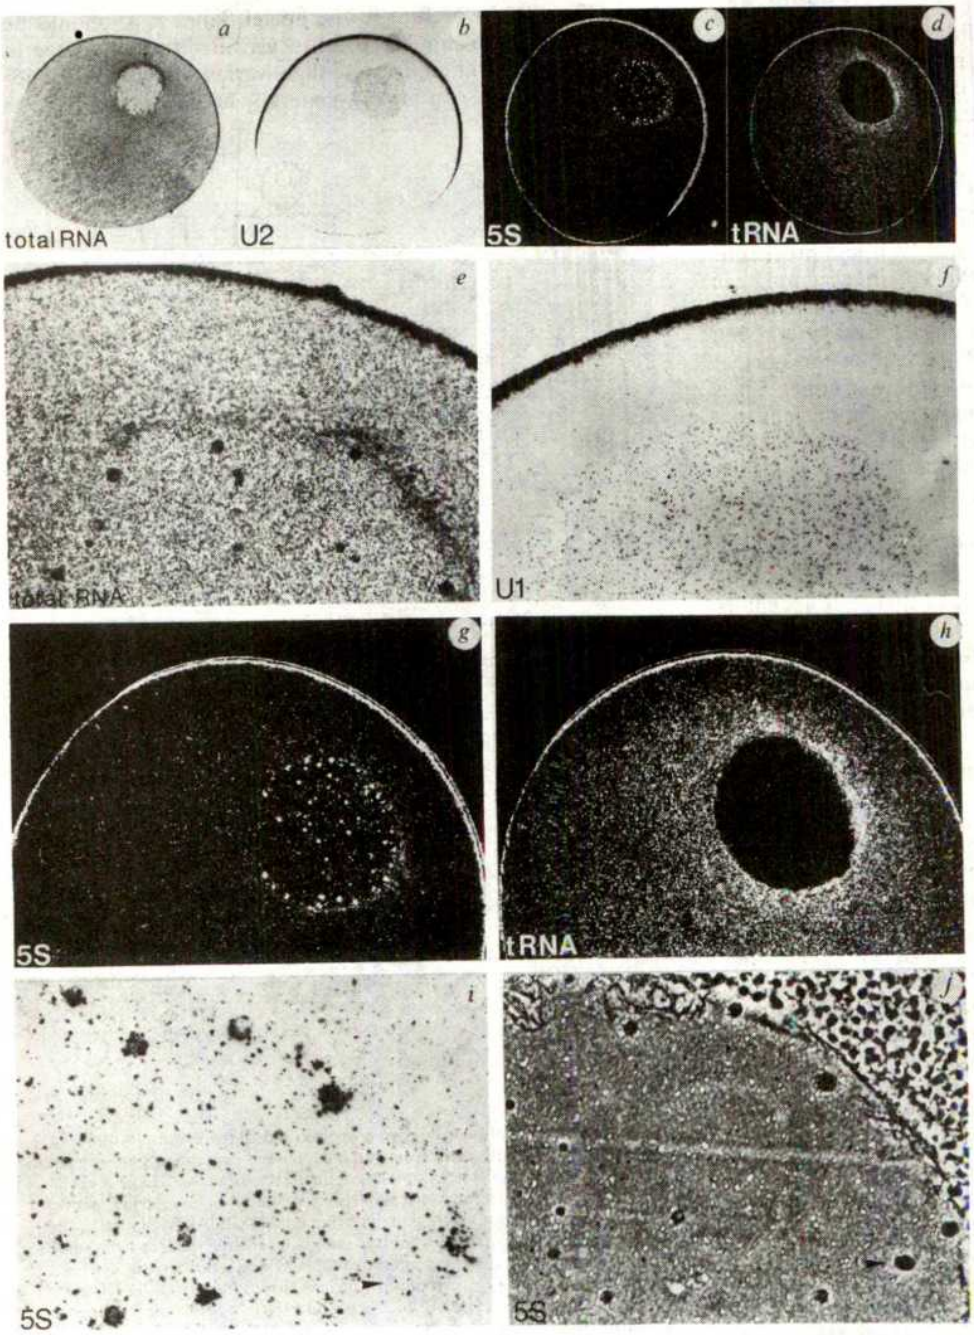

Fig. 2 Intracellular distribution of ^{3}H-RNAs from HeLa cells microinjected into the cytoplasm of frog oocytes. Total or individual RNAs (eluted from polyacrylamide gels[6]) were localized by autoradiography of sections of fixed oocytes. *a*, Total RNA; *b*, U2 RNA; *c*, 5S RNA (dark field); *d*, tRNA (dark field); *e*, total RNA; *f*, U1 RNA; *g*, 5S RNA (dark field); *h*, tRNA (dark field); *i*, 5S (transmission microscopy); *j*, same field as *i* but in phase contrast. Oocytes were fixed in San Felice fixative, embedded in paraffin, sectioned and dipped for autoradiography according to standard histological practice[39]. The radioactivity can be seen as dark grains. The black material on the oocyte periphery is pigment, present mostly in the animal hemisphere of frog oocytes. Some sections (for example *h*) show more grains in the juxtanuclear region because this part of the oocyte frequently does not contain yolk platelets (and thus effectively has more cytoplasm). Each oocyte has a diameter of ~1.2 mm. Individual nucleoli differ considerably in the extent of 5S RNA migration, as can be seen by comparing Fig. 4, *i* and *j*. A nucleolus that is not labelled at all is arrowed in Fig. 4*i*, which may correlate with the variability known to exist in the transcriptional activity of individual nucleoli in fully grown frog oocytes[42].

much U1 and U2 RNA is present in the nucleus as in the cytoplasm (determined by densitometry of autoradiograms) in individual oocytes, indicating that they are 30–60 times more concentrated in the nuclear fraction. Other less abundant snRNAs (U4, U5, U6) also migrate to the nucleus but longer exposures are required to visualize them (see Fig. 3, lane *d*). In most of the experiments reported here, samples were analysed 18–24 h after microinjection, but in time course tests a half-maximal nuclear concentration of snRNAs was already achieved by 3–4 h.

In the experiment described above, the HeLa RNAs were deposited in the oocyte cytoplasm. It could be argued, however, that this is a very artificial situation, for these RNAs are normally synthesized in the nucleus. We therefore compared the RNA distribution after injection into either the cytoplasm (Fig. 1, lanes *e*, *f*) or the nucleus (Fig. 1, lanes g, *h*). The results show that essentially the same distribution is achieved regardless of the site where the RNA was deposited, except in the case of U3 RNA, which is stable when injected into the nucleus (Fig. 1, lane *h*) but largely degraded when injected into the cytoplasm. The control indicating that the RNA was indeed injected in the oocyte nucleus is provided by high-molecular-weight material (presumably containing 18S RNA, ribosomal RNA degradation products and DNA) that runs near the top of the gel, which does not migrate and remains at the site of the injection (either in the cytoplasm, Fig. 1, lane *e*, or in the nucleus, Fig. 1, lane *h*). This control is essential because there is often reflux of material into the cytoplasm during nuclear injection[22]. When we analysed a series of 20 individual oocytes injected into the nucleus, only two presented negligible leakage into the cytoplasmic fraction (although some material had been introduced into the nucleus in 80% of the attempts). This type of experiment is technically difficult and requires analysis of many single oocytes, but it is interesting that it can be done at all, for this opens new possibilities in the study of RNA transport (such as, can a mature mRNA without intervening sequences be transported out of the nucleus?). In fact, the experiment shown in Fig. 1, lanes *g*, *h*, suggests that the transport of tRNA from nucleus to cytoplasm does not depend on the simultaneous processing of longer precursor tRNAs.

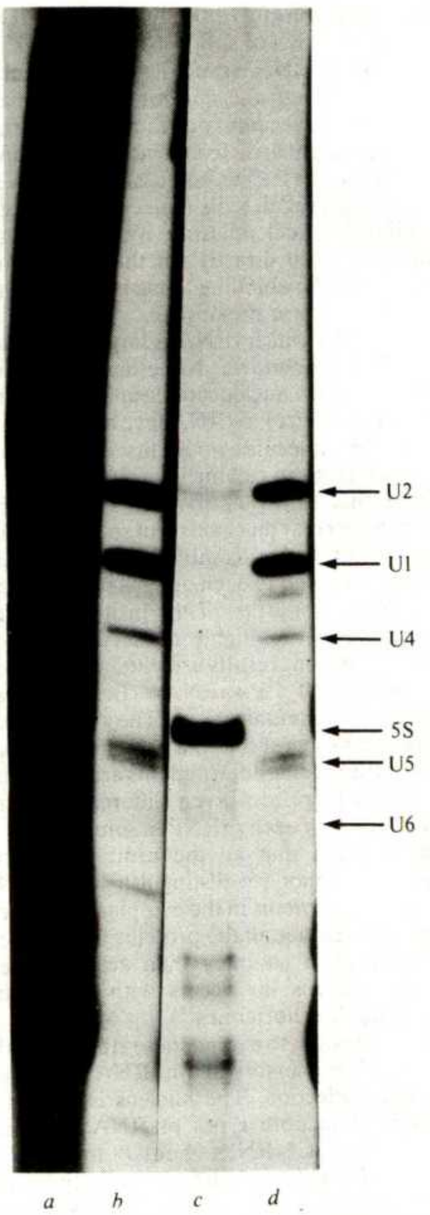

Fig. 3 Immunoprecipitation of microinjected HeLa ^{32}P-RNAs with anti-Sm lupus erythematosus antibodies. The antibodies do not react with naked RNA and therefore immunoprecipitation reflects association with oocyte proteins. Lane *a*, immunosupernatant of 8 injected oocytes; *b*, immunoprecipitate from *a*; *c*, immunosupernatant of 10 manually isolated nuclei from microinjected oocytes; *d*, immunoprecipitate from the 10 oocyte nuclei. Note that essentially all the snRNA that migrates into the nucleus is bound by the lupus antibodies. The oocyte cytoplasm contains nucleases which degraded the RNA in sample *a* during the immunoprecipitation procedure. The protein-bound snRNAs seem to be less sensitive to degradation. The nucleases are not present in the oocyte nucleus (lane *c*). For immunoprecipitation, 20 μl of serum were bound to 40 μl of a suspension containing one part staphyllococcal protein A–Sepharose beads (Pharmacia) and three parts Ipp buffer (0.5 M NaCl, 0.1% NP-40, 10 mM Tris-HCl, *p*H 8.0) in 1.5 ml Eppendorph tubes for 2 h at room temperature with end-over-end rotation, washed three times with 1 ml of Ipp buffer and then incubated with oocyte extract (nuclei isolated and homogenized in 0.5 ml PBS) for 2 h. After three 10-min washes with Ipp buffer the beads were digested for 20 min at 37 °C with 1.5 ml of proteinase K-SDS buffer and the RNAs extracted as for Fig. 1. Note that, in lane *d*, the less abundant snRNAs (U4, U5, U6) also migrate into the nucleus and bind to oocyte proteins.

Concentration of microinjected 5S RNA in the nucleoli

The cytological location of the injected RNAs was analysed by injecting ^{3}H-uridine-labelled HeLa RNAs into the cytoplasm of oocytes which 24 h later were fixed, embedded in paraffin, sectioned and autoradiographed. When oocytes injected with total HeLa RNA were examined (Fig. 2*a*, *e*) autoradiographic grains were found in both the nucleus and cytoplasm, as expected from the electrophoresis results, but the nucleoli also were intensely labelled. Analysis of the distribution of individual RNAs purified by elution from polyacrylamide gels showed that U1 (Fig. 2*f*) and U2 (Fig. 2*b*) snRNAs became concentrated uniformly in the nucleoplasm, whereas tRNA remained predominantly in the cytoplasm as expected (Fig. 2*d*, *h*). Purified 5S RNA, in addition to labelling uniformly in cytoplasm and nucleoplasm, clearly accumulated in the nucleoli (Fig. 2*c*, *g*).

The nucleolar migration of 5S RNA is not entirely surprising. In *Xenopus* oocytes the genes for 18S, 28S and 5.8S ribosomal RNAs are amplified early in oogenesis[23,24] and stored in about 1,000 extrachromosomal nucleoli, where they are transcribed. The 5S genes, on the other hand, are not located in the nucleoli but in the telomeres of most *Xenopus* chromosomes[25]. As ribosomes are known to be assembled at the nucleoli, 5S RNA must somehow migrate through the nucleoplasm before being incorporated into the immature ribosomal subunits at the nucleolus. In the nucleolus, the 5S RNA was located in the most external part (barely recognizable in some of the nucleoli shown in Fig. 2*i*, but clearly visible under the microscope), which in amphibian oocytes is known to contain the maturing ribosomal subunits which give this 'granular zone' its electron microscopic morphology[26]. Thus it is conceivable—but by no means proved—that the injected 5S RNA may become incorporated into nascent ribosomes.

Microinjected snRNAs associate with oocyte proteins

Investigation of whether snRNAs bind to oocyte components after microinjection was greatly facilitated by the discovery[27–29] that human autoantibodies from some patients with lupus erythematosus react with small nuclear ribonucleoproteins (snRNPs) but not with the naked snRNAs. We screened a collection of human sera with antinuclear antibodies (L. Mather, T. Nyffenegger, R.F.P. and E.D.R., in preparation) and obtained antisera with anti-Sm (which precipitates U1, U2, U4, U5 and U6 snRNPs) and anti-U1-RNP (which reacts only with U1-RNPs). Lanes *b* and *d* of Fig. 3 show that U1, U2, U4, U5 and U6 snRNAs are immunoprecipitable by anti-Sm antibodies after microinjection, and U1-RNA by anti-U1-RNP (not shown). Thus the HeLa RNAs bind to oocyte proteins. Essentially all the snRNAs that migrate into the nucleus are bound to oocyte proteins, whereas the nuclear-migrating 5S RNA is not recognized by this particular type of antibody (compare lanes *c* and *d* of Fig. 3).

Having established that the microinjected snRNAs accumulate in the nucleus in a ribonucleoprotein form, we then investigated whether the proteins bind to them in the nucleus or the cytoplasm, using *Xenopus* oocytes which can be manually enucleated and then microinjected in the surviving cytoplasm[30]. Figure 4 shows that about the same amount of snRNA is precipitated by anti-Sm antibodies after microinjection into nucleated or enucleated oocytes. Similar results were obtained with anti-U1-RNP antibodies. Thus the injected RNAs can bind to at least some of the snRNA binding proteins in the cytoplasm before entering the nucleus.

Small nuclear RNAs injected into enucleated oocytes together with 5 mg ml^{-1} cycloheximide (known to inhibit protein synthesis by >95%)[31] were precipitated equally well by lupus antibodies, suggesting that the cytoplasm contains an excess of pre-existing free RNA-binding proteins. Although these proteins have not been titrated, a minimum estimate is that they are sufficient to saturate the snRNAs extracted from 1,000 HeLa cells (amount of RNA microinjected per oocyte in Fig. 4).

Conclusions and prospects

The results show that microinjected snRNAs can migrate from the cytoplasm into the nucleus, where they become concentrated 30–60 fold. A similar distribution is attained irrespective of whether the material is injected into the cytoplasm or the

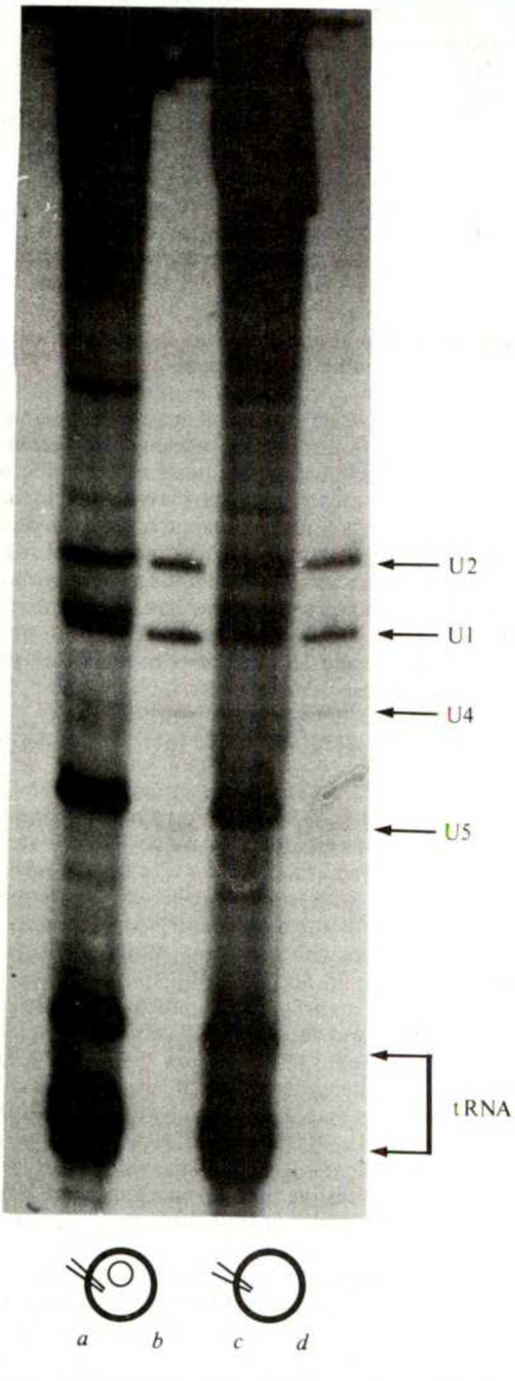

Fig. 4 Immunoprecipitation of HeLa ^{32}P-RNAs after microinjection into nucleated (*a*, *b*) or enucleated (*c*, *d*) frog oocytes with lupus anti-Sm antibodies. Ten oocytes of each type were injected and incubated for 6 h at 19 °C in enucleation 'healing buffer'[30], after which they were homogenized in PBS, and one half immediately extracted with phenol/chloroform (*a*, *c*) and the other half immunoprecipitated (*b*, *d*) with lupus antibodies. U4, U5 and U6 snRNAs were also detected in lanes *b* and *d* after longer exposure of this gel.

nucleus. Thus the nuclear membrane does not seem to be an obstacle for the movement of at least some low-molecular-weight RNAs. The nuclear affinity of snRNAs resembles that displayed by a variety of nuclear-migrating proteins (described in the introduction). Previous work with pulse-labelled cultured cells has demonstrated that newly synthesized snRNAs are not tightly bound to the nuclear fraction[19,32,33], and in *Amoeba proteus* transplanted with ^{3}H-uridine-labelled nuclei, the labelled material can migrate into the host nucleus[14,34]; these are probably manifestations of the phenomenon described here for frog oocytes. The oocyte system, however, differs in that purified, naked, RNA molecules can be introduced, and therefore it could provide a useful test system with which to determine the biological function(s) of snRNAs.

Microinjected 5S RNA accumulates in the nucleoli. It is interesting that although the nucleolus is not enveloped by a membrane, 5S RNA accumulates there. It is perhaps easy to conceive how this might arise from binding to specific sites (such as maturing ribosomes). One could similarly envisage how a whole nucleus might regulate its molecular exchanges via binding to non-diffusible nucleoplasmic components; however our experiments do not test directly whether nuclear migration of snRNAs is controlled by binding to intranuclear components or at the level of the nuclear membrane.

The mechanism by which tRNA is largely excluded from the nucleus (Fig. 2*h*) is unknown. Nonetheless, the behaviour of tRNA illustrates how nucleocytoplasmic transport could be important for gene control: if tRNA levels were to regulate their own synthesis, the molecules would first have to gain access to the genes by entering the cell nucleus.

It is hoped that lupus antibodies[29] will facilitate future analyses of the molecular mechanism of snRNA accumulation in nuclei. That a heterologous combination of human RNAs and frog proteins should bind to each other is not surprising because both the antigenic properties of the proteins and the snRNA nucleotide sequences are highly conserved in evolution[20,35]. Furthermore, equivalent results are obtained by microinjecting *Xenopus* cultured cell ^{32}P-snRNAs (E. Ackermann and J. Gurdon, personal communication). The results obtained with enucleated oocytes suggest that the proteins responsible for the Sm and U1-RNP antigenic determinants are stored in the oocyte cytoplasm, but as there are seven different proteins and one molecule of U-RNA in each snRNP in somatic cells[27], this does not necessarily mean that all the proteins are cytoplasmic. Consequently we cannot yet distinguish whether the injected snRNAs bind some proteins in the cytoplasm and then to others in the nucleus, or whether all the proteins bind in the cytoplasm and the RNA–protein complex then acquires the ability to migrate to the nucleus (as occurs with cytoplasmic steroid receptors after binding hormones[36]).

It would be interesting to extend these studies to other nuclear RNAs, like tRNA precursors and hnRNA, provided they are stable after microinjection. The nucleus is known to contain proteins that bind to both types of RNA[8,37,38] and hnRNA probably also has U1-RNPs bound to the intervening sequences[20], all of which could provide affinity for the nucleus. In the meantime, it is encouraging that at least some aspects of the transport of snRNA and 5S RNA against a concentration gradient can be approached in injected living cells.

We thank Dr L. Matter and his patients for generous gifts of antisera, Dr Georges Köhler for suggesting the immunoprecipitation method, W. Gehring, R. White, E. Ackerman, J. B. Gurdon and R. Zeller for comments on the manuscript and Mirjam Bollag for help in its preparation.

Alignment of randomly distributed objects

E. J. Zuiderwijk

Royal Greenwich Observatory, Herstmonceux Castle, Hailsham, Sussex BN27 1RP, UK

Recently, Edmunds and George[1] discussed alignments of randomly distributed quasars, following the discovery by Arp and Hazard[2] of several conspicuously aligned 'triplets' of quasars with widely disparate redshifts. If the probability of such alignments occurring by chance is very small, a physical association between the objects could be suspected[2], implying a non-cosmological component in some of the quasar redshifts. A similar problem concerning supposed alignments of megalithic sites[3] has prompted substantial analysis of the statistics of such colinearities in random sets of objects[3,4]. Here I use the angular definition of alignment to estimate the significance of the quasar triplets and confirm the results of computer simulations[1], showing that it is not improbable for these alignments to occur by chance.

The angular criterion to define alignment of three points was first used systematically by Broadbent[3]: two points I and J somewhere in an area A (Fig. 1) are said to be aligned within a small acceptance angle ε on a third point P if the angle between the lines connecting P and I, and P and J is between $\pi-\varepsilon$ and $\pi+\varepsilon$. This definition is more suitable for analysis than one in terms of the distance of P to the line connecting I and J being small[1], because the probability of finding an alignment does not depend on the dimensions of the area, and is therefore independent of the surface density of points, as long as their number is kept constant. Furthermore, the present definition ensures that three points can represent only one alignment (I and P are not aligned on J). It is easily envisaged how the probability of alignment can be computed: two points, for example, I and P, define two fan-shaped areas each with top angle 2ε. The condition for alignment will be satisfied if a third point is located somewhere in this area. Of course, we have to consider many possible separations of I and P, each defining a different area of the fans.

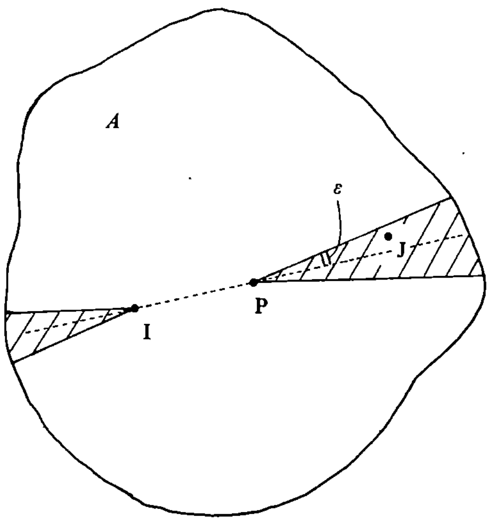

Fig. 1 Geometry of alignment for randomly distributed objects in area A. I and J are aligned on P within an angle ε.

A preliminary estimate of the probability P_ε of having an alignment of three randomly distributed points within angle ε can be obtained as follows. The average distance of the two randomly distributed points I and P is roughly half the typical diameter of the area A: two fans with $\varepsilon=90.0°$ will cover on average about half the surface. Consequently $P_\varepsilon \sim 0.5\,\varepsilon/90$, which for $\varepsilon=1°$ yields $P_{1°} \sim 1/180 = 0.00556$. Note that although the size of the area considered does not affect the value of P_ε, its shape does. This can be understood by comparing, for example, a square region with a very long but narrow area; randomly distributed objects in the latter case are bound to have a much higher chance to form an alignment. Kendall and Kendall[4] give exact values for probabilities of alignment on the 1° acceptance criterion of $1/180=0.005556$ (0.00554) and $1/180\times\pi/3=0.005818$ (0.00580) for a circular and square area respectively (numbers between parentheses indicate the probabilities as measured from 10^6 trial fields, each with three randomly distributed points). For small angles, P_ε is proportional[4] to ε. The quasar field studied by Arp and Hazard[2] is rectangular and measures about 40×50 arc min. In this case the probabilities for a square field have to be multiplied by the Broadbent coefficient[3,4] $\frac{1}{2}(s+1/s)$ with $s=40/50$, which results in $P_{1°}=0.005960$ (0.00596).

We now want to determine the probabilities of multiple alignments for N objects present in the area. Given the value of P_ε, the probabilities $P(N,K,P_\varepsilon)$ to find K alignments within an angle ε in N randomly distributed objects can be expressed in the form $P(N-1,K,P_\varepsilon)$:

$$P(N,K,P_\varepsilon)=\sum_{L=0}^{K} P(N-1,L,P_\varepsilon)\cdot B\left[\binom{N-1}{2},K-L,P_\varepsilon\right]$$

$$K\leqslant\binom{N}{3},\qquad N>3$$

The coefficients B represent the probability of finding $K-L$ alignments out of the $\binom{N-1}{2}$ combinations between two of the $N-1$ objects and the newly added Nth object. Assuming that all combinations are independent, while each combination has probability P_ε to be an alignment, B is given by the binomial distribution:

$$B(I,J,P_\varepsilon)=\binom{I}{J}P_\varepsilon^{J}(1-P_\varepsilon)^{I-J}$$

All probabilities can now be computed because by definition:

$$P(3,0,P_\varepsilon)=1.0-P_\varepsilon \quad\text{and}\quad P(3,1,P_\varepsilon)=P_\varepsilon$$

N points on a straight line represent $\binom{N}{3}$ alignments, which is

0028–0836/82/070577—02$01.00

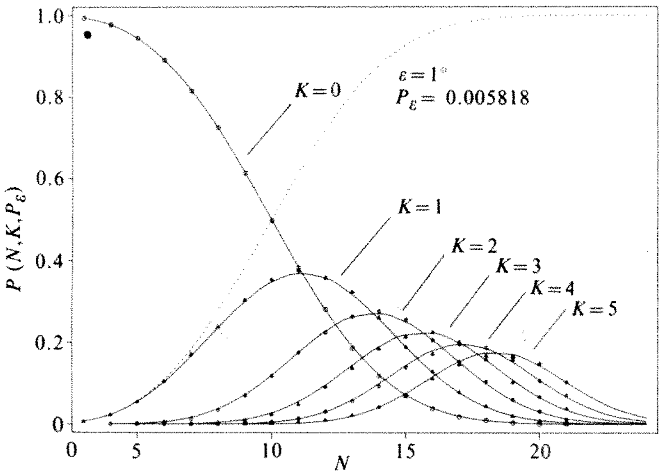

Fig. 2 Theoretical probabilities for K alignments within an angle of 1° in N randomly distributed points, here shown as smooth curves. Symbols along the curves indicate the probabilities as measured from simulations of random fields. The dashed curve represents the probability to find at least one alignment as a function of N. The presence of alignments within 1° is expected in every other field with 10 objects (the expected number of triplets per 10 points[4] is 0.698).

therefore the maximum value that K can attain. The average (expected) number of alignments equals $\binom{N}{3}P_\varepsilon$ (ref. 4). Figure 2 shows predicted probabilities for up to five alignments as a function of N. The decrease in likelihood after the initial increase with N is due to the growing chance of finding one more alignment. Computer simulations were performed using 40,000 trial random fields for N up to 10; in view of the rapid increase with N of processing time per field, the number of trials was gradually reduced to 5,000 for $N=20$.

To estimate the probability of having two aligned triplets of quasars in the field studied by Arp and Hazard[2] we have to establish the alignment angles ε. Because the exact positions of these quasars have not been previously published, they were measured on a glass copy of the ESO QB sky survey, using the RGO Coradograph and standard astrometry reduction methods (Table 1). Alignment of angles of 0.48° ± 0.14° and 0.56° ± 0.20° are easily computed in spherical trigonometry. The probability of having two alignments within 0.56° is $P(6,2,P_{0.56°})=2.0\times10^{-3}$. Because for small N and ε the distribution of the number of colinear triplets is close to the poissonian (see ref. 3), a rough estimate of the probability of obtaining two alignments can be made in this case by using the expected number of alignments ($0.00596\times0.56\times\binom{6}{3}=0.0668$); the chance of getting two from a Poisson variable with that expectation is 2.08×10^{-3}. Thus the occurrence of these aligned triplets by chance is not at all unlikely when it is realized that this particular field is part of a survey of about 5,000 quasars covering an area of ~500 square degrees (C. Hazard, personal communication). Moreover, we would expect many similar configurations to exist on the sky; the presence of two more alignments[2] in the area at 11 h 46 min + 11° with nine objects is not surprising as $P(9,2,P_{1°})=0.074$.

Table 1 Positions, accurate to about 0.8″, of quasars[2] in two aligned triplets at 11 h 30 min + 11°, and alignment angles ε

	α (1950)	δ (1950)	ε

Oxygen evolution on tantalum–polypyrrole–platinum anodes

Gerald Cooper, Rommel Noufi*, Arthur J. Frank & Arthur J. Nozik

Photoconversion Research Branch and * Photovoltaic Program
Office, Solar Energy Research Institute, Golden,
Colorado 80401, USA

Electrically conducting polymer films of polypyrrole were previously reported[1–6] to provide greatly enhanced stability against the photodegradation of semiconductor photoanodes in electrochemical photovoltaic cells. To determine the feasibility of protecting photoanodes with polypyrrole in photoelectrolysis cells where O_2 is evolved some basic questions had to be answered. To achieve this we have performed experiments using polypyrrole films as protective coatings on Ta metal electrodes; Ta is known to form insulating oxides that prevent O_2 evolution from aqueous solution. We found that polypyrrole is stable in the presence of O_2; that while polypyrrole itself is a poor electrocatalyst for O_2 evolution, metal catalysts can be deposited on its surface to enhance O_2 evolution; and that Ta–polypyrrole–Pt electrode structures are electrochemically indistinguishable from naked Pt electrodes with respect to O_2 evolution.

Recent research[1–6] has shown that electrically conducting polypyrrole films can be easily electrodeposited on n-type semiconductor electrodes, thereby imparting to the electrode greatly enhanced stability against anodic photodegradation in photoelectrochemical cells. This effect has been demonstrated[1–6] for n-type Si, GaAs, CdS, CdSe, and CdTe electrodes operating in contact with aqueous electrolyte in photovoltaic-type photoelectrochemical cells. In those experiments, electroactive redox couples, such as Fe^{3+}/Fe^{2+} or $Fe(CN)_6{}^{3-}/Fe(CN)_6{}^{4-}$, are added to the aqueous electrolyte to facilitate positive hole transfer to the electrolyte to inhibit self-oxidation of the semiconductor electrode; the net product of such cells is electrical power[7–11].

A more difficult application of conducting polymer-coated semiconductor electrodes is in the photoelectrolysis-type of photoelectrochemical cell. Here, the polymer film must protect the n-type semiconductor electrode against photooxidation in the presence of the oxygen evolution reaction in aqueous electrolyte. The oxidation of water to oxygen is a relatively difficult four-electron reaction and therefore requires positive holes with a rather positive redox potential. Holes created and utilized at such high positive potentials in photoexcited semiconductor electrodes generally result in oxidation of the semiconductor itself in addition to, or even to the exclusion of, the oxidation of water. A few large band-gap oxide semiconductors (such as TiO_2, $SrTiO_3$ and Fe_2O_3) show exceptions to this behaviour. The role of the polypyrrole film in photoelectrolysis cells would therefore be to channel preferentially the photogenerated holes in smaller band-gap and non-oxide semiconductors to the H_2O/O_2 redox couple at a rate that is much faster than the self-oxidation rate of the semiconductor.

Before the above application of polypyrrole films can be realized, the following questions must be answered. (1) Is poly-

0028-0836/82/070578—03$01.00

pyrrole itself stable in O_2-evolving conditions? (2) Can the water oxidation reaction be confined to the outermost polypyrrole–liquid interface so that physical destruction of the film by internal gas evolution can be prevented? (3) Can polypyrrole act as a sufficiently good electrocatalyst for O_2 evolution, and if not can a catalytic agent be deposited on the film surface to achieve good O_2 evolution rates?

Affirmative answers to these questions have been obtained from studies of polypyrrole films deposited on tantalum metal electrodes. Normally, Ta electrodes do not evolve O_2 because of the spontaneous development of thick tantalum oxide layers on the surface at potentials less positive than the H_2O/O_2 redox potential. Ta electrodes therefore provide a good system for testing the ability of polypyrrole to prevent substrate oxidation and to answer the above three problems.

Polypyrrole films were electrochemically deposited in a three-electrode, potentiostatically controlled cell containing a deaerated, aqueous solution of about 1 M pyrrole with 2.0 M LiCl supporting electrolyte at pH ~0.5. Rapid deposition of the polymer on the Ta substrate occurred at a potential of about +0.7 V (versus SCE). Below this potential the rapid, initial growth rate would decrease quickly to almost zero, probably because of competitive oxide film growth. At about +0.7 V (SCE) or higher, the growth rate appeared to be diffusion controlled only.

The Ta substrates were freshly ground with 600 grit SiC paper (scratch depth ~0.25 μm) before deposition to remove the insulating oxide layer and to provide for excellent film adhesion. Films grown on polished Ta surfaces readily peeled off whereas they stuck tenaciously to rougher surfaces. The area exposed to solution during film polymerization was 1.3 cm^2; this resulted in a circular spot of polypyrrole 1.3 cm in diameter at the centre of a 2.5 × 2.5 cm square Ta sample.

In some experiments, Pt was ion-beam sputtered onto the polypyrrole disk using an Ar ion beam. In these cases, a mask was used with a hole having a smaller diameter than the polypyrrole film. This ensured that no direct electrical contact was possible between the Pt and the Ta. The ion beam deposition rate for Pt was calculated by measuring the thickness of a thick Pt sputtered film with an interferometer and dividing by the sputter time. Pt film thicknesses used in subsequent experiments were then calculated from this sputter rate and the sputter time.

Electrochemical measurements were performed on the electrodes in 2 M phosphate buffer (pH = 6.7); the thermodynamic potential for water oxidation at this pH is +0.60 V (SCE). The working electrode area was defined by a pressure seal having a diameter less than the Pt film diameter; this ensured that only the Pt coated polypyrrole was in contact with the solution.

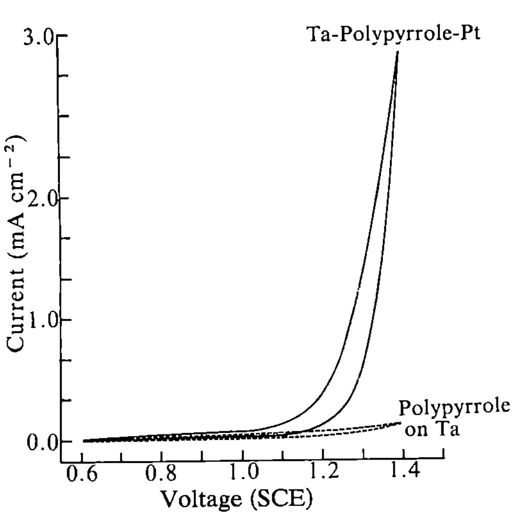

Fig. 1 Dashed line is the current–voltage characteristic of a 2.5 μm polypyrrole film on tantalum. The solid line is the current–voltage characteristic of a Pt-coated (72 Å) polypyrrole film (5 μm) on tantalum. In both cases data are shown for the sample after it was cycled 15 times from 0.6 to 1.0 V (SCE). These latter data are indistinguishable from those for a naked Pt electrode. A Ta electrode showed essentially zero current (after the oxide formed) out to 1.4 V (SCE) and beyond.

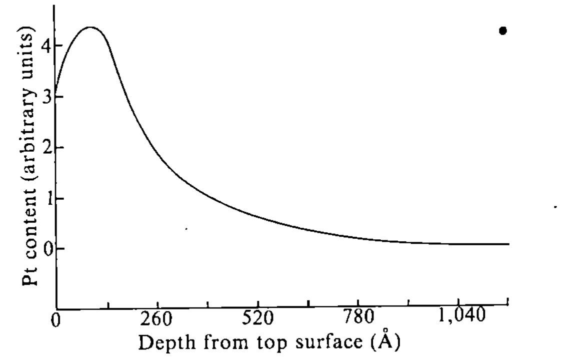

Fig. 2 Auger depth profile analysis for Pt for a Pt-coated (45 Å) polypyrrole film (12.5 μm) on tantalum. The Pt is mainly confined to the outer 100 Å, and decays to zero at ~800–900 Å.

Experiments with Ta electrodes and with just polypyrrole on Ta showed that O_2 could not be evolved from Ta metal and that polypyrrole is a poor catalytic surface for H_2O oxidation. As seen in Fig. 1, O_2 could not be readily evolved from a polypolypyrrole surface even at 1.4 V (SCE); the data represented by the dashed lines in Fig. 1 are for a 2.5 μm polypyrrole film on Ta. Initially the electrode was cycled between +0.6 and 1.0 V (SCE) 15 times to oxidize completely the polypyrrole film and thus eliminate interferring anodic current arising from polypyrrole oxidation; fully oxidized polypyrrole is required for high film conductivity.[12–14]. The sample was then cycled from +0.6 to +1.4 V (SCE); the maximum generated current density in these conditions was <0.2 mA cm^{-2}. In contrast to this behaviour, a smooth, naked Pt electrode (formed by ion-beam sputtering) developed a current density of ~1 mA cm^{-2} at 1.3 V (SCE); this is about the minimum current density necessary to observe the formation of O_2 bubbles. At 1.4 V (SCE) the current density increased to about 3 mA cm^{-2}.

When a thin film of Pt (~72 Å) was sputter-deposited on the surface of polypyrrole-coated Ta, O_2 evolution occurred (confirmed by observing bubbles) at the same potential that it appeared on the naked Pt electrode and at approximately the same current density (1.3 mA cm^{-2}). Figure 1 (solid lines) shows a typical current versus voltage curve for the Ta–polypyrrole–Pt electrodes we studied. Cyclic sweeps between +0.6 and +1.1 V (SCE) were performed before O_2 evolution for the same reasons given above. Inspection of Fig. 1 and comparison of current versus time plots for naked Pt and Ta–polypyrrole–Pt samples indicate that the electrochemical behaviour of the Ta–polypyrrole–Pt electrode is indistinguishable from that of the naked Pt electrode with respect to O_2 evolution.

The polypyrrole film thicknesses studied ranged from 0.45 to 12.5 μm; they all showed O_2 evolution on Ta substrates. Despite these relatively thick films, the question could be raised concerning Pt penetrating through the polypyrrole film and reaching the Ta surface thereby short circuiting the polypyrrole (Pt deposited on Ta also behaves as a naked Pt electrode with respect to O_2 evolution). To rule out this possibility, a Ta electrode with a 6.2 μm polypyrrole film and with about 45 Å of Pt sputtered onto the surface was examined using Auger spectroscopy to determine the elemental profile perpendicular to the surface. In this technique a 1-mm diameter Ar ion-beam drills a hole into the sample while a 1/8 mm electron beam simultaneously impinges on the walls of the hole. The Pt profile, determined by the peak-to-peak amplitude of the characteristic 1970 eV Auger electron signal of Pt, has a maximum at ~100 Å and then decays to background noise levels at ~800–900 Å depth below the surface (see Fig. 2). The fact that a peak exists at 100 Å and that Pt is detected down to ~800–900 Å below the surface is probably due to entrainment of Pt atoms by the polymer matrix due to collisions with the Ar ion-beam, and momentum transfer in the forward beam direction. In any event, Pt clearly cannot short out any of the films studied.

It was also observed that the thinner polypyrrole films (0.45 μm) were more physically stable than the thicker films. The latter tended to blister after the passage of about 1 C of charge. The thin films showed no visible deterioration after the passage of several coulombs and were very adherent and scratch resistant.

We conclude that an electrochemically deposited polypyrrole film can be used to protect a metal surface from self-oxidation in conditions where O_2 is being evolved and where the metal would normally form an insulating oxide layer. Because of its high conductivity, the film can efficiently transfer charge over large distances (12.5 μm). We have thus shown that the electrochemical production of O_2 on Ta–polypyrrole–Pt electrodes is almost indistinguishable from naked Pt electrodes. Polypyrrole itself cannot evolve O_2 because it is a poor electrocatalyst for the O_2 evolution reaction. However, an electrocatalyst, such as Pt, can be deposited on the surface to ease O_2 evolution. The O_2 evolution reaction can be confined to the outermost polypyrrole–water interface, and the film is rather stable both physically and chemically in O_2-evolving conditions; this is especially true for thin polypyrrole films. The results are encouraging with respect to the potential application of polypyrrole films to stabilize small band gap and non-oxide n-type semiconductors for O_2 evolution in photoelectrolysis cells.

We thank Terence M. Thomas for the Auger depth-profile analyses. This work was supported by the Office of Basic Energy Sciences, Division of Chemical Sciences, US Department of Energy, under contract EG-77-C-01-4042.

Penetration of water into hot rock boundaries of magma at Grímsvötn

H. Björnsson, S. Björnsson & Th. Sigurgeirsson

Science Institute, University of Iceland, Dunhaga 3, 107 Reykjavík, Iceland

The Grímsvötn geothermal area is located within one of the most active caldera volcanoes in Iceland in the interior of the ice cap Vatnajökull at an altitude of 1,400 m (Fig. 1). Its setting offers unique conditions for calorimetric measurement of the heat release from the subglacial geothermal system. The melting of ice due to the geothermal activity creates a depression in the surface of the ice cap. Ice and water are diverted towards the depression from a 300 km² drainage basin. The meltwater accumulates in a 30 km² subglacial lake. Periodic outbursts of water (jökulhlaups) drain the lake subglacially down to the Skeidarársandur plain. We propose here that penetration of water into hot rock is the primary reason for the intense heat release (5,000 MW thermal) of the subglacial Grimsvötn geothermal area. Injection of water into boundary rocks of magma should be considered as a method of heat exploitation.

The history of Grímsvötn has been studied extensively[1] and the first report on a jökulhlaup dates back to AD 1332. From 1600 until 1934 about one jökulhlaup occurred each decade with an estimated discharge of 6–7 km^3 of water, but since 1934 there have been two outbursts per decade and the observed volume correspondingly smaller, 3–3.5 km^3 (refs 1,2). A long-term mass balance of the drainage basin has been given elsewhere[3]. The average accumulation in the form of ice is equivalent to 2,200 mm yr^{-1} of water and the surface ablation amounts to 500 mm yr^{-1}. A long-term steady-state model for the drainage basin proves to be a valid approximation[3]. The water added to the lake is 6.6×10^{11} kg yr^{-1}. About 1.5×10^{11} kg yr^{-1} are melted at the glacier surface by meteorological processes, but the difference, about 5×10^{11} kg yr^{-1} is melted by geothermal heat within the drainage basin. The heat flux required to melt this ice is ~5,000 MW (thermal). The geothermal activity responsible for the melting of the ice is not limited to the lake but scattered over a large area, estimated to be up to 100 km^2. If the heat released at Grimsvötn is averaged over 100 km^2 we obtain an average heat flux density of 50 W m^{-2} or some 1,200 h.f.u. To illustrate the dimension of this heat flux, note that it is equivalent to the average global heat flow through an area of 80,000 km^2 or nearly the whole area of Iceland.

Magma is commonly assumed to be the source of heat for high-temperature geothermal systems. A heat output of 5,000 MW is equivalent to the heat released by solidification and cooling of $\sim5\times10^7$ m^3 yr^{-1} of magma down to a temperature of 400 °C. A magma volume of at least 20 km^3 is required to maintain the present heat output at Grímsvötn over the 400 yr of reported jökulhlaups. Given a magmatic source of this size the extraction of heat at the observed rate is still problematic. A conducting wall separating stagnant magma and a hydrothermal system could supply the observed heat flux for a short period after intrusion of the magma, but the wall would soon thicken as magma solidified and the flux would decline below the observed rate.

The difficulty of explaining the thermal output of high temperature systems by conduction from a magmatic source has been recognized[4–6]: Banwell[5] considered steam released from convecting magma to act as a heat carrier. Water could penetrate to the magma through a few deep faults, and diffuse into the magma, but be released when it had circulated to some higher level where the pressure is lower.

White[6] proposed alternatives for the Steamboat Springs systems, either a convection within a magma chamber maintaining magmatic temperatures near the base of the hydrothermal circulation or a fissure system controlling the circulating water and gradually extending deeper into the batholith, as stored heat was removed at higher levels by circulating water. Irvine[7] described a convective process in a magma body where crystals accumulate in the lower part of the intrusion but the temperature near the top remains close to, or above, the liquidus temperature of the magma. This process allows higher rate of heat loss and solidification than would occur if the crystals were frozen to the roof of the magma chamber. Bodvarsson[4] favoured penetration of water into the hot rock boundary of intrusions to compensate for the increased thickness of the solidifying rock that insulated the molten lava from the hydrothermal system. Lister[8] has presented a conceptual model of the downward penetration of water into hot rocks by a process of cooling, thermal contraction and cracking. The cracks enable the water to penetrate to the horizon of solidification, although the horizon proceeds downwards. Thermal insulation of the rock is no longer an effective barrier for heat removal as the water is steadily penetrating into new, hot rock and carrying its heat away by convection.

Models of a replenished chamber of convecting magma or steam released from convecting magma, might explain the heat output at Grímsvötn. Recent field evidence obtained by watering of a molten lava flow, however, suggests that the process of penetration of water into hot rock is most likely to be respon-

0028-0836/82/070580—02$01.00

sible for the heat extraction at Grímsvötn. During the Heimaey eruption in Iceland in 1973 water was pumped onto the molten lava in attempts to impede the flow and divert it away from the town. A flow of 100 kg of water per second, applied in one place, spread over some 7,000 m^2 of lava, which was engulfed in steam. Drillholes revealed that after two weeks of watering the solidification of the lava had progressed to a depth of ~12 m, leaving the solidified lava at the temperature of saturated steam, that is 100 °C. Temperature logs of the holes indicated that the transition layer, where the temperature rose from 100 to 1,050 °C, was only a fraction of a metre thick during watering. Excavation of lava after the eruption revealed that the structure of water-cooled lava was greatly different from the structure of large jointed blocks where no water had been applied during the solidification. The water-cooled rock was intensely fractured and broken into pieces commonly 10–20 cm across. The structure resembled entablature lava, a formation frequently found in river beds and canyons, where a lava flow has solidified under floods of river water, dammed up by the lava flow[9]. Each cubic metre of lava which solidifies and cools down to 100 °C releases sufficient heat to evaporate 1.4 m^3 of water. To evaporate 100 kg s^{-1} of water spread over 7,000 m^2 of lava the heat flux density must have been ~40 kW m^{-2}.

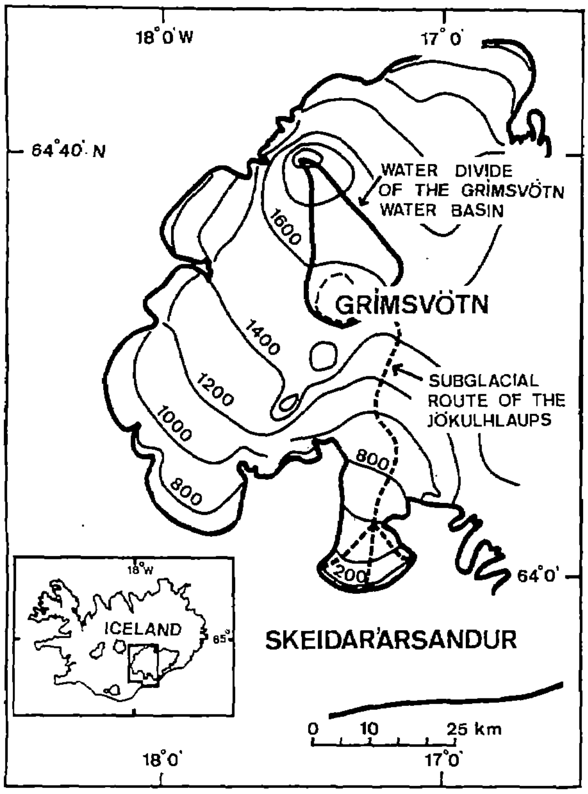

Fig. 1 Location of Grimsvötn geothermal area within the Vatnajökull ice cap in Iceland.

The propagation rate of the front of solidification was 12 m in 14 days or 0.9 m per day. In model calculations one may view this process as stationary, seen from the solidification boundary. Instead of considering the boundary progressing downward at a constant rate, one may, in calculations, assume that the boundary is fixed, but the lava is moving upwards and solidifying as it passes the fixed boundary. Just above the boundary there is a thin transition layer of solid, uncracked rock, where the heat flux is carried by the moving rock and by conduction. The first cracks which appear above this layer are narrow and filled with superheated steam but the bulk of the rock above has shrunk by cooling and developed cracks wide enough to admit percolation of a mixture of water and saturated steam. Simple calculations based on this model give 0.1 m for the thickness of the conductive transition layer.

There is every possibility that the effective extraction of heat by watering of hot rock at Heimaey can also take place at the boundaries of magma bodies or intrusions at a depth of several kilometres, if water is readily available. The process acts in hot rocks close to solidus temperature, irrespective of whether the heat source is a regular confined magma chamber or a swarm of magma sheets, completely or partially molten. There are, however, two reasons to expect lower heat flux densities than in the surface lava. First, due to higher overburden pressure at depth the cracks will open up at a lower temperature. Second, the heat is transported upwards by a one-phase fluid at pressures exceeding the critical pressure of water[8].

Returning to the problem of heat transfer from the Grímsvötn caldera, a magmatic source of heat must be inferred, but its size and depth has not been investigated. Observations of S-wave shadows at the Krafla caldera in the Northern Volcanic Zone of Iceland suggest a magma body at 3–7 km depth beneath that caldera[10]. Its horizontal extent is ~8 km^2. Assuming 10 km^2 for a similar body under Grímsvötn, water penetrating into that body would have to propagate at an average rate of 5 m yr^{-1} to yield the observed flux of 5,000 MW. At the deep end of the geothermal system, where the temperature may be near 400 °C, a mass flux of 2,400 kg s^{-1} of water is required to transport the extracted heat up to the bottom of the glacier. Vertical permeability is likely to be favourable near the ring fractures of the caldera. A special feature at Grímsvötn is the cyclic loading of the caldera by accumulation of meltwater for 5 yr and a drop of the water level of the lake by 100 m in one week during jökulhlaups. This sudden drop in pressure might help to keep fractures open and it has even been suggested that it could excite magma and lead to eruptions, which sometimes have been observed to coincide with jökulhlaups[1].

The above considerations have important implications for the exploitation of geothermal systems which derive heat from an underlying magma body. Drilling of wells for injection of water into the hot rock boundary might accelerate the heat extraction and aid in the generation of steam, where water is deficient, or the access of water to the magma body is hindered by an impermeable barrier. Controlled injection of water might even be used to establish reservoir conditions in temperature, pressure and fluid saturation which are optimal for the exploitation. There are some indications that the Krafla geothermal system[11] in Iceland might be a water-deficient system of this kind. On the other hand, abundant supply of water might explain the fact that geothermal systems with the highest natural heat output in Iceland are found in subglacial areas[12–14].

Reports on problems associated with sampling, handling and measuring interstitial waters[1–5] have led to a refinement in methodology, but apart from the introduction of *in situ* sampling, techniques have not fundamental changed. The *in situ* techniques include a hydraulically operated device for filtering samples at pre-selected sediment depths on the ocean floor[6,7], and the insertion of dialysis membranes into sediments where they are left to equilibrate[8,9]. The former method requires specialized unwieldy equipment, and the latter necessitates a return to the sampling site. We report here a new method for measuring Fe (II), Mn (II) and sulphide ions in the interstitial waters of anoxic sediments which have been sampled using a simple corer. Rapid filtration directly into a polarographic vessel permits the extraction of interstitial water and the measurement of all three components <5 min after subsampling the sediment. The non-destructive polarographic measurement is able to assess the extent of contamination by oxygen and to study subsequent reactions in the interstitial water.

Previous workers[4,5] have noted that Fe(II) in interstitial water can be readily oxidized which can lead to erroneously low results for Fe(II) determinations. Scavenging by the freshly formed Fe(III) species can distort the analysis of trace metals, silica and phosphate[5]. Recommendations for handling in oxygen-free conditions have therefore been made[4,5] but glove box techniques can be laborious and monitoring oxidation which occurs during handling is difficult. Complications are introduced by the need either to squeeze under high pressure or to centrifuge to obtain sufficient sample for analysis. Observations in our laboratory have shown that equilibration using dialysis membranes is unsuitable for sediment rich in iron and sulphide, because FeS may precipitate inside the membrane and so total analysis for iron and sulphide does not give equilibrium concentrations in solution. Polarography unambiguously measures, on as little as 1 ml of sample, solution species of unique oxidation state[10]. Such a small volume may be obtained by simple hand filtration and refinements, such as small filter pore sizes, are unnecessary because the technique distinguishes the soluble component. Moreover, the technique functions best in the oxygen-free conditions which these waters provide.

Jenkin cores[11] of the sediment–water interface were taken from Esthwaite Water[12] and Rostherne Mere[13], both seasonally anoxic lakes with organic-rich fine sediments, using core tubes with pre-drilled 3 mm diameter holes at 5 mm depth intervals and sealed with polythene tape. A 20 ml disposable syringe fitted with a 7.5 cm 12 G stainless-steel needle was flushed several times with N_2 and then used to remove a 10 ml subsample of sediment. A 47 mm Swin-Lok (Nucleopore) filter holder, containing a Whatmans GF/C glass fibre filter, was fitted with 10 cm of 0.5 mm bore polythene tubing which led to the bottom of a standard Metrohm EA-800-5 polarographic cell assembly containing three electrodes: hanging mercury drop, platinum wire and calomel. The cell was flushed with a controlled gas mixture of Ar and CO_2 and the filter holder was flushed with N_2. Immediately the N_2 stream was disconnected from the filter assembly the syringe of sediment was attached. 1–2 minutes of hand pressure on the syringe provided the necessary 1–5 ml of sample for measurement. A polarographic scan from 0 to 1.7 V was immediately initiated while the Ar–CO_2 mixture was flushed over the surface of the liquid. Trials with various filter assemblies indicated that a unit with a large dead volume, in this case 3–4 ml, was needed because the wide passages prevented constriction and allowed rapid movement of slurry and also ensured that there was sufficient volume to accommodate the particulate material in proximity to the filter. It was possible to use Whatmans GF/F or Millipore 0.45 µm filters if the filtration time was extended.

Figure 1 shows typical polarographic scans of the overlying water and interstitial water. The polarography of anoxic lake water has been well documented[14,15] and measurements on interstitial waters have recently been reported[16]. The named peaks in Fig. 1 have been well characterized and the pre-wave at −1.1V has been attributed to interactions between Fe^{2+} and sulphide[14]. Determination of sulphide, Fe (II) and Mn (II) in a single scan is particularly useful because iron and manganese reflect the redox conditions of the sediments and are often major components in the interstitial waters[17]. Ferrous sulphide is usually a controlling solid phase. Figure 1 indicates that iron is dominant and sulphide is restricted to undetectable (<0.3 µmol l^{-1}) levels in the interstitial waters of Esthwaite Water, whereas in Rostherne Mere sediments the higher sulphate concentration of the overlying water (0.58 mmol l^{-1} compared with 0.13 mmol l^{-1} for Esthwaite Water) allows sulphide to dominate and suppress the iron. Respective concentrations (in µmol l^{-1}) of sulphide, Fe (II) and Mn (II) taken from Fig. 1 are: for overlying Esthwaite Water 4, 110 and 42; for interstitial Esthwaite Water <0.3, 550 and 53; and for interstitial Rostherne Mere 15, 1.7 and 370. Measurement of the *p*H of interstitial Esthwaite Water

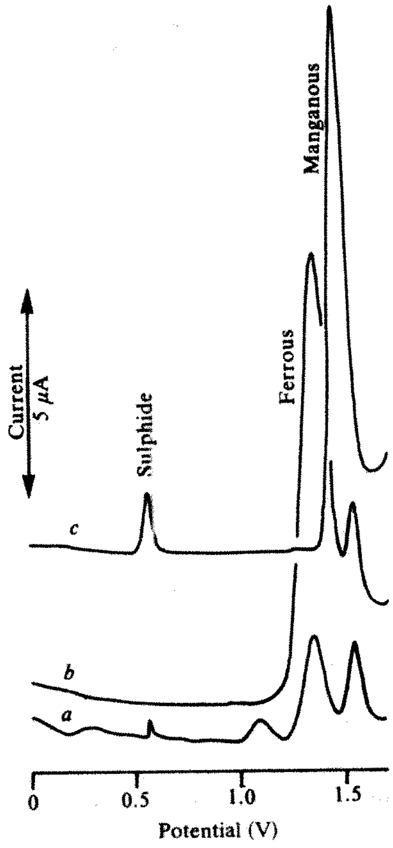

Fig. 1 Differential pulse polarograms (current versus potential) of *a*, the overlying lake water of Esthwaite Water; *b*, interstitial water of Esthwaite Water; and *c*, interstitial water of Rostherne Mere. The interstitial water samples were from a sediment depth of 3–4 cm. Samples *a* and *b* are for 8 September 1981 and sample *c* for 30 September 1981.

0028-0836/82/070582—02$01.00

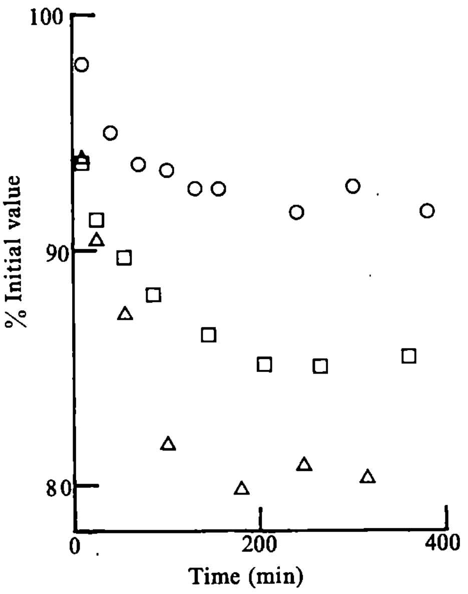

Fig. 2 Decay of Fe (II) with time. ○, No stirring, sampled on 23 September 1981; △, bubbling with $Ar–Co_2$, sampled on 24 September 1981; □, with magnetic stirring, sampled on 29 September 1981. All samples are from Esthwaite Water sediment at a depth of 4–5 cm.

by inserting an electrode into a filtered sample and extrapolating to zero time gives a value of 6.94 which agrees well with the value of 6.88 from an electrode inserted directly into the sediment. For Rostherne Mere, however, values from analogous measurements differ and are 7.1 (extracted) and 6.8 (direct). The overlying water is known to have a pH of 7.13 (10 °C)[18]. Therefore the solubility product, $pK_{sp}^{NBS} = a_{Fe^{2+}} \cdot a_{HS^-}/(H^+)$, can be calculated using documented activity coefficients[19] to be 2.71 for overlying Esthwaite Water, >3.45–3.55 for Esthwaite interstitial water and 4.05–4.55 for Rostherne Mere interstitial water. The result for the overlying water is in good agreement with previous work[18,19]. Both interstitial waters seem to exhibit a reduced solubility and, because the solid phase has more opportunity to age in the sediment than in the anoxic waters of the lake, support is given to the supposition that the ageing solid phase controls the interstitial water concentrations[19,20]. This result, and the small Mn (II) gradient and large Fe (II) gradient across the sediment–water interface, which agrees with previous water column measurements[12], show how useful is this simple handling technique. The method should be applicable to organic-rich marine sediments, although the Fe (II) and Mn (II) peaks will be closer together[21,22]. Because anodic stripping voltammetry uses the same equipment this simple procedure could be used to measure trace metals in interstitial water.

Changes in the concentration of pore water components after extraction from the sediment have previously been noted[4]. Because polarography is a non-destructive technique any change may be continuously monitored on the same sample. Figure 2 shows the change in Fe (II), as a percentage of the initial measured value, with time, for a quiescent solution, one stirred with a magnetic flea and one bubbled with an $Ar–CO_2$ mixture with, in order to preserve a constant pH of 6.94, the same partial pressure of CO_2 as that in the pore water (corrections for loss by volatilization have been made). Ferrous iron decays to a new lower equilibrium value when the solution is stirred. This result cannot be readily attributed to an oxidation effect because bubbling with the inert gases results in a lower equilibrium value and Mn (II), which has much slower oxidation kinetics[23], also shows an initial decay. In all solutions Mn (II) was reduced to 95% of the initial signal after 10 min and thereafter remained constant. Moreover the polarographic technique is able to measure oxygen directly in the sample[15] and show that it was never initially greater than 4 μmol l^{-1}. This introduced oxygen was quickly consumed (<5 min) by the solution to undetectable quantities, but it would be insufficient to account for >100 μmol l^{-1} of Fe (II) which were removed after 200 min (Fig. 2). It must be concluded that once pore water is extracted a re-equilibrium occurs which, contrary to previous conclusions[4,5], need not be linked to oxidation, loss of CO_2 or changes in pH.

Laboratories, Berkeley, Gloucestershire GL13 9PB, UK

The dissolution of metal oxides that are normally insoluble in aqueous solution is an important process in the transport of corrosion products around the circuits of water-cooled nuclear reactors[1], and in reactor decontamination[2,3]. It has recently been shown[4–6] that one-electron reducing agents dissolve iron (III) oxides, often at much faster rates than the more conventional reagents such as chelating agents and strong acids. In appropriate conditions the products of water radiolysis can be used to generate the one-electron reducing reagents in the form of free radicals. We report here our preliminary results on the radiation-induced dissolution of colloidal Fe_2O_3 by propan-2-ol radicals, $Me_2\dot{C}OH$, in acidic aqueous solution.

Colloidal Fe_2O_3 was prepared by the method of Matijevic *et al.*[7]. Aqueous solutions containing 3×10^{-2} mol dm^{-3} $FeCl_3$ and 5×10^{-3} mol dm^{-3} HCl were refluxed for 2 weeks at 100 °C. The colloidal particles were spherical, with diameters of 0.5–1.5 μm as shown by electron microscopy of the dry material and by particle sizing of the colloidal solution. The latter measurements showed that the mean diameter of the particles was 0.9 μm and the FWHM of the diameter distribution 0.6 μm. These parameters changed little from one preparation to another.

Irradiations were carried out using ^{60}Co γ rays at dose rates of 0.15–0.8 krad min^{-1} on solutions at pH 2.2 containing $\sim 10^{-13}$ mol dm^{-3} Fe_2O_3 particles and 10^{-1} mol dm^{-3} propan-2-ol, saturated with N_2O. In these conditions the following sequence

0028–0836/82/070583—03$01.00

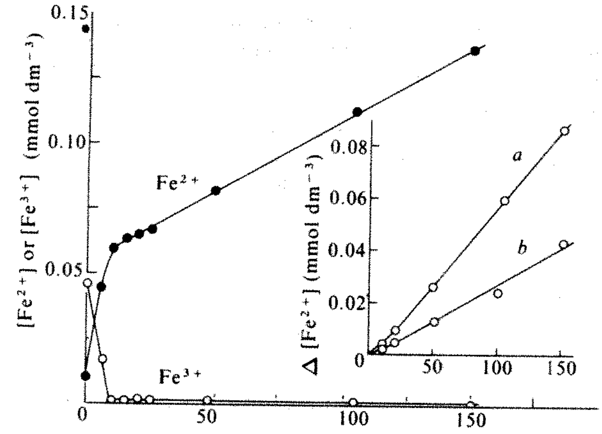

Fig. 1 Fe^{2+} formed in the reduction of Fe^{3+} and colloidal Fe_2O_3 by $Me_2\dot{C}OH$. Inset: effect of dose rate on the rate of formation of Fe^{2+} from Fe_2O_3. *a*, 0.17 krad min^{-1}; *b*, 0.82 krad min^{-1}.

of reactions generates propan-2-ol radicals with $G(Me_2\dot{C}OH) = 7$, where G is the radiation chemical yield in molecules $(100\ eV)^{-1}$.

$$H_2O \rightsquigarrow e^-_{aq}, H, OH, H_2, H_2O_2 \tag{1}$$

$$e^-_{aq} + N_2O \rightarrow N_2 + O^-(\xrightarrow{H_2O} OH + OH^-) \tag{2}$$

$$OH \text{ or } H + Me_2CHOH \rightarrow Me_2\dot{C}OH + H_2O \text{ or } H_2 \tag{3}$$

After an irradiation the remaining colloidal Fe_2O_3 was removed by centrifuging and the dissolved iron was measured as Fe(II) using *o*-phenanthroline, either as Fe(II) alone or as total iron after reducing Fe(III) with hydroxylamine.

Figure 1 summarizes the results. The high initial yield of Fe^{2+} is due to the reduction (reaction (4)) of Fe^{3+} present in the colloidal preparation ($\sim 6 \times 10^{-5}$ mol dm^{-3}), and the lower yield represents the reduction of Fe(III) in the colloidal particles. On the basis that the competing reactions involving $Me_2\dot{C}OH$ after the initial Fe^{3+} has been reduced are (5) and (6), the observed dose rate effect (Fig. 1 inset) is consistent with reaction (5) being diffusion controlled.

$$Me_2\dot{C}OH + Fe^{3+} \rightarrow Fe^{2+} + Me_2CO + H^+ \tag{4}$$

$$Me_2\dot{C}OH + Fe(III)_{colloid} \rightarrow Fe^{2+} + Me_2CO + H^+ \tag{5}$$

$$2\ Me_2\dot{C}OH \rightarrow Me_2CO + Me_2CHOH \tag{6}$$

Experiments in the absence of propan-2-ol and N_2O show that hydrogen atoms formed in reactions (1) and (7) also bring about dissolution of Fe_2O_3

$$e^-_{aq} + H^+ \rightarrow H \tag{7}$$

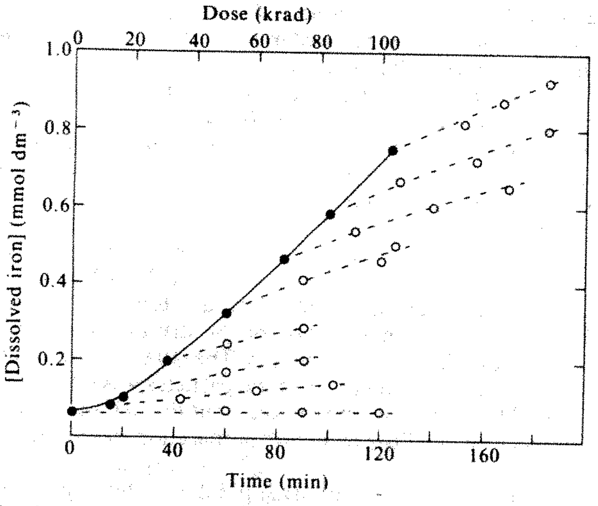

Fig. 2 Radiation-induced (●) and thermal (○) dissolution of colloidal Fe_2O_3 by Fe(II)–EDTA.

Reaction (6) competes favourably with reaction (5) because of the low concentration of colloidal particles ($\sim 10^{-13}$ mol dm^{-3}) and this is a limiting factor to the rates of dissolution which can be achieved. However, this problem can be overcome by adding EDTA to the system, as shown by Fig. 2. In the presence of 10^{-3} mol dm^{-3} EDTA the rate of radiation-induced dissolution is greatly enhanced and when the irradiation is stopped the dissolution process continues at a rate which depends on the radiation dose. The explanation for these effects is that dissolved Fe^{2+} complexes with EDTA to form Fe(II)–EDTA which undergoes reaction (8) with the colloidal Fe_2O_3 and $Me_2\dot{C}OH$ now reduces Fe(III)–EDTA in reaction (9)

$$Fe(II)\text{–}EDTA + Fe(III)_{colloid} \rightarrow Fe^{2+} + Fe(III)\text{–}EDTA \tag{8}$$

$$Me_2\dot{C}OH + Fe(III)\text{–}EDTA \rightarrow Fe(II)\text{–}EDTA + Me_2CO + H^+ \tag{9}$$

Because reaction (9) occurs in the bulk solution and [Fe(III)–EDTA] ≫ $[Me_2\dot{C}OH]$, reaction (6) cannot compete with it. From the measured rates of thermal dissolution we calculate $k_8 = 2 \times 10^9\ dm^3\ mol^{-1}\ s^{-1}$, indicating that reaction (8) is $\sim 10^3$-fold slower than diffusion controlled.

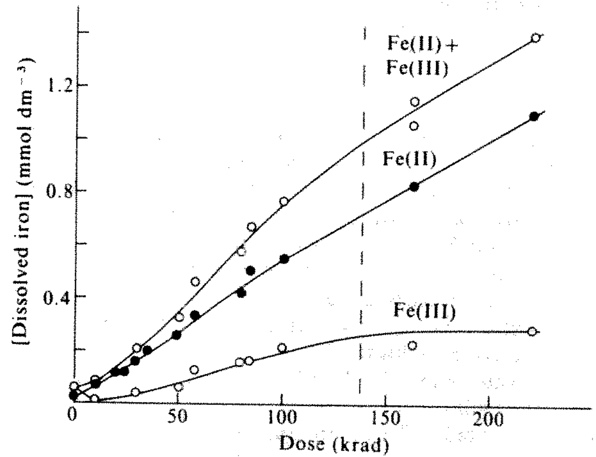

Fig. 3 Radiation-induced dissolution of Fe_2O_3 by Fe(II)–EDTA. The vertical broken line shows the dose at which no uncomplexed EDTA remains.

Ultimately, sufficient dissolved iron is produced to complex all the EDTA. When this state is reached the rate of dissolution of the colloid will be limited by the rate of reaction (9) provided sufficient Fe(III)–EDTA remains in solution (see Fig. 3). However, $G(Fe^{2+}) \sim 5$ instead of 7 ($= G(Me_2\dot{C}OH)$ as expected. This discrepancy is attributed to a reaction of $Me_2\dot{C}OH$ with the EDTA or an impurity introduced with it, because G(Fe(II)) from solutions of Fe(III)–EDTA in the absence of Fe_2O_3 followed a similar pattern. $G(Me_2CO) = 7.7$ was obtained in both cases, which is the expected result if all $Me_2\dot{C}OH$ is oxidized because $G(H_2O_2)$ (see reaction (1)) is 0.7 and H_2O_2 also generates $Me_2\dot{C}OH$ through reactions (10) and (3)

$$H_2O_2 + Fe(II) \rightarrow Fe(III) + OH + OH^- \tag{10}$$

Two points of wider implications emerge from this work. First, water radiolysis leading to the generation of reducing free radicals may bring about dissolution of corrosion products in the reactor core. There is growing evidence[8,9] that radiolysis enhances the corrosion rates of certain materials and, although several other factors are involved, there is good reason to believe that the intermediacy of species such as the hydrated electron will increase the rate of release of iron from corroded surfaces in radiation zones. The second point is the potentially important part played by complexes of iron(II), such as Fe(II)–EDTA, in reactor decontamination. Many commercial reactor decontaminating reagents are composed of mixtures of organic acids and complexants. These alone tend to be poor at effecting the dissolution of iron (III)-containing oxides, although some dissolution may occur, for instance, by corrosion of the underlying metal to give Fe^{2+} in solution. We suggest that complexes of this ferrous ion give rise to a further, and possibly much more rapid, autocatalytic dissolution. Recent experiments show the dissolution of haematite powder by oxalic acid to occur by an autocatalytic process of this type (R.M.S., unpublished data).

Uranium–lead system in fragments of a single zircon grain

Urs Schärer & Claude J. Allègre

Laboratoire de Géochimie et Cosmochimie, Institut de Physique du Globe et Département des Sciences de la Terre, Universités Paris VI et VII, 4 place Jussieu, 75230 Paris Cedex 5, France

Since the demonstration that U–Pb analyses of zircon fractions[1] (from a few grains up to several thousand grains or fragments of grains[2]) or single zircon grains[3,4] yield reliable radiometric age data, this method has been widely applied to igneous, metamorphic and sedimentary rocks. The present investigation of U–Pb systems for a suite of distinct fragments of a single zircon grain from a 1,093$\pm^{21}_{18}$-Myr old syenite of the Pikes Peak batholith (Colorado, USA) demonstrates that uranium is heterogeneously distributed in this zircon crystal. Most parts of the grain suffered various degrees of lead loss, the others show a closed-system behaviour. We show that degrees of lead loss are not correlated with uranium concentrations of the fragments.

In contrast to other U-bearing minerals such as monazite and sphene, zircons often show an open-system behaviour for lead defining discordant age patterns (^{206}Pb/^{238}U age < ^{207}Pb/^{235}U age < ^{207}Pb/^{206}Pb age). The most common presentation of U–Pb age data is as the Concordia diagram[5] in which ^{206}Pb/^{238}U is plotted against ^{207}Pb/^{235}U (with reference to the Concordia curve). The perturbations of the U–Pb systems creating the discordancies in zircon are interpreted as being mainly due to either continuous lead diffusion[6,7], or episodic lead loss[5,8]. In many cases a combined diffusion–episodic model[9,10] or a multi-stage episodic lead loss model[9,10] is needed to explain the data. Uranium gain[11] has also been suggested as an important cause of discordant U–Pb ages.

Our main aim was to elucidate the U–Pb systematics in a single zircon grain. In contrast with previous work which was based on zircon fraction—or single—grain measurements, the present study focused on distinct fragments within a single zircon grain. For comparison, a grain by grain U–Pb dating of zircon and coexisting allanite/chevkinite was carried out. Both minerals were extracted from a quartz–fayalite–syenite body (B65D) from the central part of the Pikes Peak batholith. The mineralogy, petrology, major/minor element chemistry and genesis of this batholith has been extensively studied by Barker and co-workers[12,13]. For the genesis of the quartz–fayalite–syenite they conclude on an alkali olivine basaltic magma which reacts with a lower crust of granulite facies. Previous K–Ar and Rb–Sr mica ages[14–19] from different lithological variants of the batholith yield ages between 930 and 1,060 Myr (recalculated for the conventional decay constants[20]). Rb–Sr whole rock isochrons determine ages of ~1,008 Myr (ref. 13) and 1,019 ± 13 Myr (ref. 14) for the emplacement of the batholith.

The zircon population of the quartz–fayalite–syenite consists of slightly coloured, transparent to yellow-brown, translucent euhedral prisms with a pronounced concentric zoning. The length-to-width ratios vary from about 1/1 to 10/1. Small grains are mainly free of microscopically visible inclusions whereas coarser crystals frequently contain different inclusions—mostly opaque phases. The analysed allanite/chevkinite are dark-red glassy subhedral grains. To verify the mineralogical composition of zircon, a series of grains was analysed for major and trace elements on the CAMECA IMS 3F ion microprobe. Tracing of profiles in single crystals showed that all grains consist of at least 98% of Zr-silicate. Therefore an intergrowth of zircon with other U-bearing mineral phases such as xenotime can be excluded. The chemical compositions (major elements and a few trace elements) of three opaque inclusions in zircon were also determined. The analyses show that the inclusions consist of Al, Fe, Ca-silicate phases with U and Th concentrations of the order of 1‰. The allanite/chevkinite grains represent a Ca, Ti, Ce, Fe-silicate as revealed by electron-microprobe analysis.

U–Pb results of the grain by grain analyses for both minerals are shown in Fig. 1 and listed in Table 1. The analysed zircon grains are free of microscopically visible inclusions. Grains 1, 2 and 7 (see Table 1 and Fig. 1) are transparent prisms with width-to-length ratios of about 1/3, whereas grains 3 and 4 show identical habits but a higher degree of radioactive damage. Crystals 5 and 6 are translucent short prisms with length-to-width ratios of ~1/1 and zircon 10 is a translucent long prismatic grain. Zircons 8 and 9 are surface-rich almost spherical transparent crystals with a well developed concentric zoning.

A regression line[21] (Fig. 1) including the data from the 10 measured zircon grains and the allanite/chevkinite grain intersects the Concordia curve at 1,097$^{+68}_{-47}$ Myr and 109 ± 150 Myr. The upper intercept age can be interpreted as the time of crystallization of zircon. The lower intercept age could be

Decay constants and atomic ratios were used according to the recommendation of IUGS[20]. After dissolution of zircon[24], element separation and purification[25] the atomic compositions and concentrations have been determined by isotopic dilution (^{205}Pb–^{233}U mixed-spike) in a Thomson THN 206 mass spectrometer. The samples were loaded with H_3PO_4 and silica gel on Re single filaments. The isotopic composition of blank common lead was determined to: 17.98±0.10 (2σ errors) for $^{206}Pb/^{204}Pb$, 15.45±0.10 for $^{207}Pb/^{204}Pb$ and 37.28±0.20 for $^{208}Pb/^{204}Pb$. The blank amount for lead varies between 40×10^{-12} g and 280×10^{-12} g with an average value of $\sim140\times10^{-12}$ g whereas the U blank lies at $\sim20\times10^{-12}$ g (the lead-blank consists of 20–40×10^{-12} g introduced by the chemical procedure and 20–260×10^{-12} g extracted from the Teflon bombs in which the zircons are dissolved; the uranium blank is mainly due to memory effects in the Teflon bombs). Taking into account the observed isotopic variation of blank common lead as well as the precisions of Pb and U measurements, the accuracies are: 1.5% for $^{206}Pb/^{238}U$, 2.0% for $^{207}Pb/^{235}U$ and 1.7% for $^{207}Pb/^{206}Pb$. The 2σ errors of the Concordia intercept ages are computed from the intersections of the asymptotes to the hyperboles that limit the confidence interval of the regression lines[21].

ND, not determined.

* Corrected for a U-blank of 20×10^{-12} g.

† Radiogenic lead corrected for blank common lead and where present (see Pb_c) corrected for incorporated common lead with: $^{206}Pb/^{204}Pb$ of 16.64, $^{207}Pb/^{204}Pb$ of 15.35 and $^{208}Pb/^{204}Pb$ of 36.58.

‡ Incorporated common lead, calculated for maximal blank common lead amount. The given values are therefore minimum concentrations.

§ No incorporated common lead detectable.

explained by different models: (1) diffusive lead loss; (2) combined diffusive–epidodic lead loss; and (3) epidodic lead loss. Previous K–Ar and Rb–Sr data[13-19] do not indicate any episodic event postdating the intrusion of the batholith, thus favouring an interpretation by a continuous lead diffusion[6,7] (Fig. 1, line *a*: volume-dependent diffusion[6], and line *b*: time-dependent diffusion[7]). On the other hand, several episodes of Tertiary volcanism[22,23] (~20–70 Myr ago) are known in areas south of the batholith, so an episodic or combined episodic –diffusion lead loss of zircon cannot be excluded. An episodic lead loss would mean that the U–Pb system in zircon is more sensitive to moderate heating than the Rb–Sr system in minerals. However, exactly discordant age pattern cannot be determined.

The concordant allanite/chevkinite grain does not plot on the regression line yielding a slightly younger age of ~1,060 Myr (upper intercept age being ~1,097 Myr). This disagreement on age could be due either to a real age difference reflecting the cooling history of the pluton or to an incorrect common lead correction. As this mineral contains a large amount of common lead (~20 p.p.m., see Table 1), the isotopic composition of which is not known, the apparent younger age could be caused by this uncertainty. The deviations of zircons 2, 4, 8 and 10 from the regression line can also be explained by an incorrect common lead correction due to unknown lead in zircon. Grains 2 and 10 with common lead concentrations of 7.5 p.p.m. and 32 p.p.m. respectively (see Table 1) are the best illustration of this observation of incorporated lead in zircon. The lead could be either primary common lead absorbed during growth of the crystal or younger common lead which diffused from the intergranular phases into zircon. Such a mechanism might take place in fissures or highly metamict parts of the grain.

The primary lead, included during growth of zircon and allanite, can be (1) common lead from an uncontaminated mantle magma, (2) common lead from a contaminating older crust, or (3) inherited radiogenic lead from U-bearing minerals from an older crust. The latter two types of lead would yield too high $^{207}Pb/^{206}Pb$ ages with respect to the real crystallization age of zircon and allanite. A weak indication for such an older lead is given by grain 8 ($^{207}Pb/^{206}Pb$ age 1,126; Table 1).

None of the deviations from the regression line can be fully explained by uncertainties of the isotopic composition of lead introduced during analysis (blank common lead, Table 1).

A zircon weighing ~0.5 mg was broken into 11 distinct fragments. The yellow-brown translucent grain showed a microscopically clearly visible igneous zoning. The fragment edges crosscut these heterogeneities and therefore the zircon parts analyses do not reflect the different growth stages of the crystal. Figure 2 shows the location of the various fragments (F_1–F_{11}) in the zircon grain. The fragments were obtained by selective breaking in an agate mortar filled with alcohol. The zircon was first broken in two parts almost equal in size (fragment F_1–F_6 and F_7–F_{11} respectively), then the upper part (F_1–F_6) was broken into three pieces, F_1, F_2 and a remaining part (F_3–F_6) which was then divided. Fragments F_7–F_{10} were separated in the same way from the other half of the crystal. In contrast with the well defined fragments F_1–F_{10}, F_{11} consisted of small splinters and therefore this fragment was analysed through two series (F_{11a} and F_{11b}) of such small pieces. Except for F_3, F_4, F_{10} (centre domains) and F_{11a} and F_{11b}, all fragments crosscut the whole crystal. The centre domains reach only to about two-thirds of the

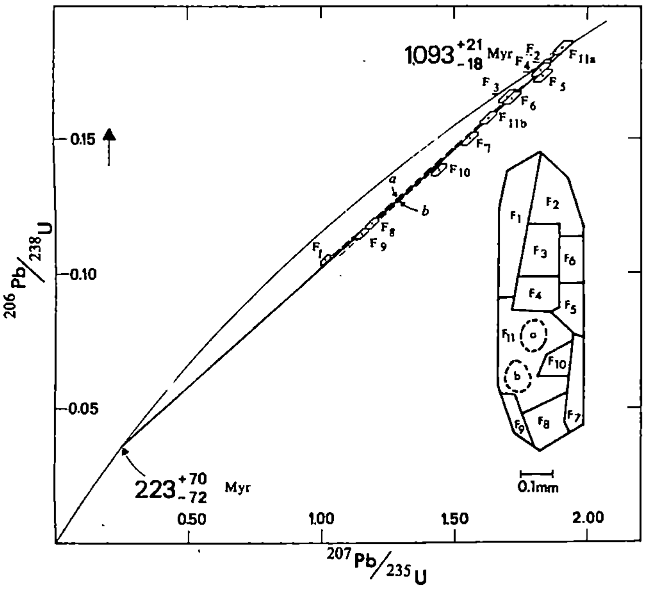

Fig. 2 Concordia diagram for U–Pb zircon fragment analyses of a single grain from a quartz–fayalite–syenite body within the Pikes Peak batholith (Colorado, USA).

depth of the crystal. The three-dimensional relationship of F_{11a} and F_{11b} is not known.

Figure 2 represents the Concordia diagram for the U–Pb fragment results (Table 1). The most remarkable observation from the fragment analyses are the concordant fragments: no concordant grains could be found. Additionally, the spread of degree of lead loss is larger than among single grains. The coexistence of concordant and strongly discordant fragments demonstrates that the U–Pb system remained closed for some crystal parts while others suffered a strong lead loss. This difference in behaviour occurs at a very small scale (<0.1 mm) as is best shown by the most discordant fragment F_1 and the adjacent concordant fragment F_2.

The concordant fragments, together with the large spread of degrees of discordance permit, for this zircon population, a more precise age determination than the grain by grain analysis. A regression line including all fragment data (Fig. 1) defines an age of $1,093^{+21}_{-18}$ Myr for the crystallization of the zircon grain (grain by grain analysis: $1,097^{+68}_{-47}$ Myr). The deviation of fragment F_5 and F_{10} could again be ascribed to an incorrect common lead correction due to small, not detectable incorporated lead in zircon.

The different degrees of lead loss are not correlated with the U concentrations of the fragments nor with their location within the grain. The most discordant fragment F_1 with a U concentration of 958 p.p.m. and the adjacent concordant fragment F_2 with a higher U concentration of 1,181 p.p.m. support these observations which strongly contrast with the other pattern observed from zircon fraction analyses (thousand of grains) which shows a positive correlation between increasing U concentrations and degree of lead loss. The most discordant grains 9 and 10 (Fig. 1) and the most discordant fragments F_1, F_8 and F_9 (Fig. 2) are characterized by unusually high common lead contents (Table 1). This observation could indicate a relationship between loss of radiogenic lead and gain of common lead.

These results suggest that the discordancy phenomenon should be discussed in terms of domains within a single grain and not in terms of grain dimensions or volume diffusion relative to grain size. Our cutting techniques do not allow us to determine domain geometry or size—further research is necessary. The variability of the common lead contents in the fragments suggests that we should consider lead loss as an exchange with the surroundings rather than as a one way process.

As the regression line coincides within analytical error to a volume-dependent[6] as well as a time-dependent[7] continuous lead diffusion model (Fig. 2, line *a* and *b* respectively), continuous lead diffusion appears to be the most plausible interpretation for the discordant U–Pb ages of the zircon fragments. However, the relatively large errors do not allow us to resolve definitively whether or not a subordinate episodic lead loss occurred. On the other hand, an episodic lead loss alone, related to the Tertiary volcanism[22,23] in the adjacent areas ~20–70 Myr ago, cannot explain the lower intercept age of 223^{+70}_{-72} Myr.

This study of one grain shows that the lead loss mechanism is more complex than generally thought and in particular probably occurs at the domain side. Thus the degree of discordancy varies through a single zircon grain and permits an accurate dating.

The age of $1,093^{+21}_{-18}$ Myr of the quartz–fayalite–syenite is significantly older than the previous Rb–Sr whole rock age[14] for the Pikes Peak batholith (1,019 ± 13 Myr). This difference could be explained in two ways: (1) the lithological variants of the Pikes Peak batholith crystallized in a time range of ~70 Myr; or (2) the Rb–Sr system in whole rocks remained open for ~70 Myr while the U–Pb system in zircon was closed from the very first moment of crystallization of the pluton. As there is no indication for a metamorphism in this rock[12,13] interpreting the younger Rb–Sr age as a reopening of the system is difficult.

We thank F. Barker and the USGS for supplying zircon and allanite, G. Manhes and D. Ben Othman for useful discussions, A. Pierre for ion probe analyses, and O. Krebs for calculating the lead diffusion lines. This is IPGP contribution NS/535.

Thermal stresses in subducting lithosphere can explain double seismic zones

L. S. House*† & K. H. Jacob*

*Lamont-Doherty Geological Observatory and
† Department of Geological Sciences, Columbia University,
Palisades, New York 10964, USA

The discovery of double-planed zones of intermediate-depth seismicity associated with subducting oceanic lithosphere (refs 1–7 and L.S.H. and K.H.J., in preparation) has generated much interest in the origin and distribution of stresses in descending plates. Several mechanisms have been proposed to explain why double zones occur[8]. Here we investigate the role of thermal stresses for the state of stress in a descending plate and test whether they can account for the observed characteristics of double seismic zones. By modelling the descending slab as a thin elastic plate and using the temperatures in the slab estimated by

0028–0836/82/070587—03$01.00

Toksöz *et al.*[9], we find that the polarities of thermally generated stresses agree with those obtained from the focal mechanisms of earthquakes in the two zones. Thermal stresses also can explain the separation between the two zones of seismicity at shallow depths and their gradual merging at greater depth.

The best studied double seismic zone is that beneath North-east Honshu, Japan (Fig. 1). Note that the double zone of seismicity occurs in a portion of the downgoing plate that appears to be straight. We sought to evaluate whether the thermal stresses that result from the warming of the plate as it descends into the mantle could produce the prominent features of most double seismic zones, as exemplified by that beneath North-east Honshu.

Toksöz *et al.*[9] have computed several physically reasonable models of temperatures in subducting slabs, from which we have chosen one that does not include the effects of shear heating, phase changes, or heat sources internal to the slab. Temperatures from this model should produce minimum estimates of thermoelastic stresses, because heating of the slab occurs only by adiabatic compression and conduction from the surrounding asthenosphere. The model in Fig. 2 assumes an 80 km thick slab which dips at 45° and subducts at a rate of 8 cm yr^{-1}.

The temperatures selected, $T(x, y)$, are at 10 km intervals along 20 profiles oriented normal to the slab and spaced at equal downdip (x) intervals of 20 km. After smoothing temperatures in the x direction, we obtain differential temperatures, $\Delta T(x + \Delta x, y) = T(x + \Delta x, y) - T(x, y)$, from successive profiles.

For initial calculations of thermal stresses we assume that the entire 80 km thickness of the plate remains elastic. Later computations modify this assumption to allow for relaxation by high temperature creep. Incremental profiles of thermoelastic stress are computed from the differential temperatures using the formulation of ref. 10, which is appropriate for a thin elastic plate free of external force or moment. As downgoing lithospheric plates have lateral dimensions at least several times their thickness, a thin-plate approximation seems reasonable. The method assumes complete relief of thermal strains in the direction normal to the plate (y; Fig. 2), thus σ_{yy} (thermal) $= 0$. Thermal stresses in the downdip (σ_{xx}) and along the strike (σ_{zz}) directions are equal and obey the relationship[10]:

$$\sigma_{xx} = [1/(1-\nu)]\left[-\alpha \Delta T E + 1/(2C) \int_{-C}^{+C} \alpha \Delta T E \,\mathrm{d}y + (3y/2C^3) \int_{-C}^{+C} \alpha \Delta T E y \,\mathrm{d}y\right] \quad (1)$$

in which ν is Poisson's ratio (0.25); α is the linear coefficient of thermal expansion, about one-third of the volumetric coefficient[11], and chosen to be 3.6×10^{-5} °C^{-1}, an average value for olivine at 800 °C (ref. 12); for E, Young's modulus, we chose a value of 9×10^5 bar, slightly less than that of olivine quoted by Birch[13]; $2C$ is the thickness of the plate. Results of the initial stress computations are shown in Figs 2 and 3*a*.

On a time scale of 10^5–10^6 yr, not all the thickness of the lithosphere will remain elastic[14]; high temperature creep may relax strains in the remainder of the plate. Experimental work[15] has suggested the following relationship for steady-state creep at differential stresses of <2 kbar:

$$\dot{\varepsilon}(\mathrm{s}^{-1}) = 70\sigma^3 \exp(-Q_\mathrm{p}(RT)^{-1}) \quad (2)$$

where σ is $\sigma_1 - \sigma_3$ (bar); Q_p is the activation energy, 122 kcal mol^{-1}; R is the gas constant, 1.986 cal K^{-1} mol^{-1}; and T is the temperature in Kelvin. The second set of computations allows for relaxation of thermal strains by creep; when the creep rate at a sample point exceeds the thermal strain rate ($\approx 10^{-17}$–10^{-18} s^{-1}), we assume that that portion of the descending plate has relaxed. We reduce the thickness of the plate ($2C$) by the amount that has relaxed, and calculate thermal stresses in the remaining portion of the plate from equation (1). The equation is not strictly applicable to a plate of variable thickness, but probably is still sufficiently accurate for the results (Fig. 3b) to be representative.

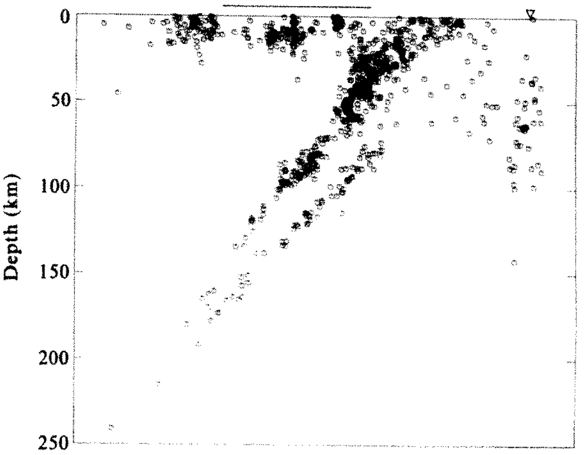

Fig. 1 Double seismic zone benaeath North-east Honshu, Japan[5]. The main features are: (1) microearthquakes between depths of ~60 and 180 km define two subparallel zones of seismicity (a down-dip length of 210 km); (2) at the shallow end, the two zones are ~40 km apart, and gradually merge at depth; (3) Hasegawa *et al.*[5] find composite focal mechanisms that indicate reverse faulting and down-dip-directed P axes for events in the upper zone, while those in the lower zone have down-dip-directed T axes. Note the 2:1 vertical exaggeration in the figure. The horizontal bar at the top of the figure is the projection of the island of Honshu; ∇ marks the position of the Japan Trench.

Stresses computed with an 80 km thick elastic slab (Fig. 3*a*) show good agreement with the characteristic features of the double seismic zone shown in Fig. 1. Stresses in individual profiles reach magnitudes of ~500 bar, which are consistent with observed stress drops of earthquakes at intermediate depths (refs 16, 17 and J. Mori, unpublished results). At shallow depths maximum tensional stresses are reached ~40 km below

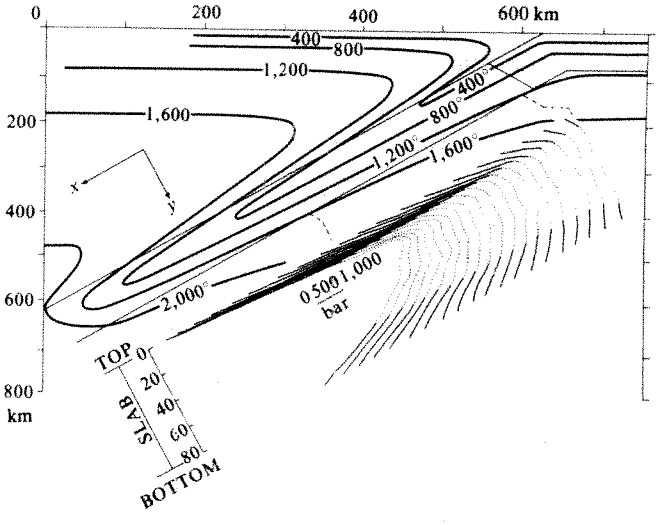

Fig. 2 Thermal model of the descending lithospheric slab and cumulative thermoelastic stresses obtained from it. Isotherms (in °C) are derived from numerical modelling of an 80 km thick slab that dips at 45° and subducts at a rate of 8 cm yr^{-1} (after ref. 9). The coordinate system used appears in the inset, upper left; $y = 0$ at the centre of the slab; the z axis points out the page (along the strike of the slab). Cumulative thermoelastic stresses calculated for the 80 km thick slab model (no relaxation) are inset in the lower right. Each successively deeper profile is the sum of the stresses from the previous profile, plus the increment of stresses developed between the profiles. Note the difference in the y scale from the main figure. Tensional stresses are indicated by the dotted portions; compressional by the solid lines. Note that cumulative tensional stresses of >2 kbar are reached only ~20 km inside the slab from where cumulative compressional stresses of 6 kbar have developed. A grid spacing of 10 km in the y direction was used in the computations; details with a comparable wavelength are unreliable. Note the horizontal exaggeration of ~1.7 in the main figure.

the plane of maximum compressional stress, which is located at the upper surface of the descending plate. The loci of maximum tension and compression appear to converge at greater depth although they do not actually merge. Cumulative stress profiles (Fig. 2) obtained by summing the successive down-dip profiles of Fig. 3*a* show similar features; note that cumulative thermal stresses reach ~6 kbar. Stress profiles obtained by allowing for relaxation (Fig. 3*b*) show loci of maximum compression and tension separated by only ~10 km. This proximity results in part from the thinness of the unrelaxed portion of the plate. High temperature creep, as calculated for Fig. 3*b*, assumes steady-state creep rates, but establishment of the latter may require strains as large as[15] 1–2%. As thermal strains are generally <0.5%, the thickness of lithosphere depicted as relaxed in Fig. 3*b* may be overestimated.

Models explaining double seismic zones by invoking phase changes[2] and unbending of the plate[3,4,6] have difficulties in explaining some of the observed seismic features, notably the downdip length over which double zones are observed[8] (see Fig. 1). Previous studies found agreement between the polarities of thermoelastic stresses and those inferred from earthquake focal mechanisms[18] and of the separation between the zones of maximum thermal tension and compression and that observed from earthquakes[19]. Our results further demonstrate that thermoelastic stresses can account for the gradual merging of the two seismic zones at depth, and that stresses resulting from unbending or phase changes in the plate are probably generated in small volumes in the downdip direction. Once relaxed (for example, by creep or fracture) such stresses are irrevocably dissipated. In contrast, thermoelastic stresses are continuously induced as the temperature increases in the plate during subduction.

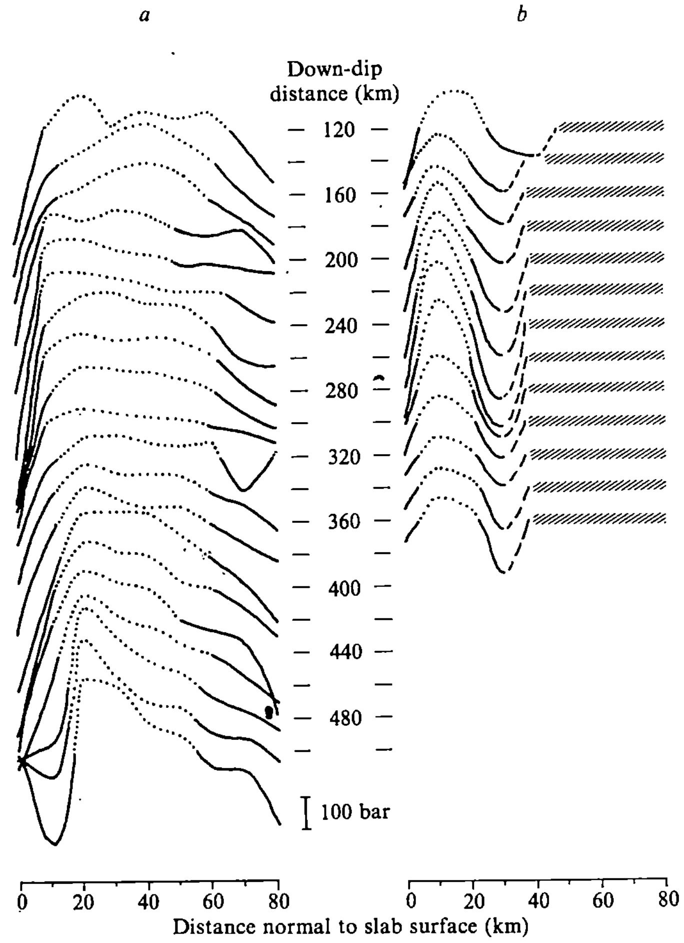

Fig. 3. *a*, Incremental thermoelastic stress profiles calculated with an 80 km thick elastic slab. As in Fig. 2, the dotted portions of each profile are tensional, the solid portions compressional. Features with a wavelength comparable with or smaller than the grid spacing (10 km) are unreliably determined. Note the narrowing of the separation between the maximum tension and compression towards the lower profiles. *b*, As *a*, except that relaxation by high temperature creep (see text) is allowed to reduce the effective elastic thickness of the slab, when relaxation approximately equals or exceeds the thermal strain rates ($\approx 10^{-18}\,s^{-1}$). Portions of the slab where relaxation has occurred are shaded. Dashed portions of the stress profiles indicate regions of transition between elastic and relaxed portions of the slab. Stress profiles are omitted below a down-dip length of 360 km; only a 20 km thickness of the lithosphere remains elastic and as temperatures are sampled at 10 km intervals, computed stresses would be unreliable.

We emphasize that the state of stress in a descending plate probably results from many factors (see refs 20–22 for example). Strain rates due to thermal effects ($\approx 10^{-17}$–$10^{-18}\,s^{-1}$) are much smaller than those resulting from bending or unbending of the downgoing plate where it undergoes maximum curvature ($\approx 10^{-15}\,s^{-1}$; in Fig. 1, maximum curvature occurs at a depth of <50 km). In the apparently straight portion of the downgoing plate, where Fig. 1 shows a double seismic zone, strain rates resulting from slight bending or unbending could be comparable with, or smaller than, those due to thermal effects. Although unbending occurs in most descending plates, double seismic zones do not[8]. Hence, double seismic zones may result from stresses of relatively small magnitude that are easily overprinted. Double seismic zones are observed only in the downgoing plates that are not strongly in either down-dip tension or compression[8].

The thermal model used above is very simple. It does not consider, for example, the effects of frictional heating[23], dehydration[24], or interactions between the downgoing plate and a convecting asthenosphere[25]. Nevertheless, the major features obtained from the model should be reliable enough to evaluate the validity of the thermal stress hypothesis.

Thermoelastic stresses seem to account for many of the major features of almost all the double seismic zones identified so far. A notable exception is the double zone beneath the Shumagin Islands region of the eastern Aleutians where there is a stress polarity in an upper seismic zone opposite to that found elsewhere—down-dip tension[7]. This is interpreted as a temporary feature related to a great earthquake that is expected to occur in the Shumagin Seismic Gap[26] in the near future and so does not necessarily contradict the model presented here.

In conclusion, we suggest that thermal stresses may strongly influence the state of stress in descending slabs of lithosphere that are not otherwise dominated by tension or compression.

New dates for the Tata, Hungary archaeological site

H. P. Schwarcz

Department of Geology, McMaster University, Hamilton, Ontario, Canada L8S 4M1

I. Skoflek

Tata Museum, Tata, Hungary

The archaeological site at Tata, 70 km WNW of Budapest, has yielded a Mousterian lithic industry of small artefacts chipped from chert pebbles, with affinity to the Quina type[1]. However, the two best known artefacts from the site are a 'churinga' carved from a piece of a mammoth tooth (Fig. 1), and an amulet with an inscribed cross, made on a polished nummulite fossil. Marshack (personal communication), who examined both the churinga and nummulite, observed that one or both arms of the cross 'engraved' on the nummulite are in fact natural fractures that penetrate through the stone. However, the ivory plaque appears to have been carefully separated from a compound molar tooth of a mammoth, shaped and bevelled, and then coloured red by rubbing with ochre. The age of this site was first determined by ^{14}C analysis of charcoal from the cultural layer[2]. The age of 55 ± 2.5 kyr led Bordes to assign the cultural material to the middle Mousterian. However, palaeontological data[3] indicate that this site was occupied towards the end of the last interglacial. Also, two single determinations of Th/U ages on travertines from the site yielded dates of 116 ± 16 kyr (ref. 4) and 70 ± 20 kyr (ref. 5), both of which are more consistent with present estimates of the time interval corresponding to the last interglacial (125–90 kyr). We report here new uranium series dates on the travertine which show that the site was occupied at ~100 kyr BP. This confirms that the amulet from this site is one of the oldest decorative artefacts known, and was presumably created by *Homo sapiens neanderthalensis*.

The cultural material of this site is all contained within lenses of loess, 1 m or less in thickness, which lie within a mound-like accumulation of spring deposited travertines. Such travertines can be dated by the Th/U method if they are relatively free of clastic impurities[6]. However, some travertines of this sequence, and in particular, those immediately over- and underlying the cultural layer, contained significant amounts of detrital contaminants. This results in the presence at the time of deposition of significant amounts of thorium, including ^{230}Th, which can interfere with the age determination. The presence of this 'common' thorium is monitored by the activity ratio ^{230}Th/^{232}Th. If this ratio is <20, then some correction is necessary to obtain a reliable estimate of the age.

Travertine samples were taken from above and below the culture layer, and aliquots were dissolved in acid; any insoluble material was discarded. Uranium and thorium were then chemically separated from the solution, plated onto steel disks, and their α activity was counted. Radiochemical data are given in Table 1. Sample 21, with a high ^{230}Th/^{232}Th value, defines a maximum age for the culture layer of 116 ± 5 kyr, for a layer of travertine ~3 m below the culture layer. Sample 40 from a layer 1 m above the culture layer, also had a high thorium ratio, and gives a minimum age for the culture layer of 78 ± 5 kyr. However, the remaining samples, which were collected immediately above and below the culture layer, all had high detrital contamination, as evidence by ^{230}Th/^{232}Th ratios <10, and abundant insoluble residues. Estimates of their ages, assuming an initial ^{230}Th/^{232}Th ratio of 1.5, are shown in Table 1, column 7, and suggest a mean age of 118 ± 37 kyr, which is not much more informative than the estimate based on the over- and underlying samples.

An alternative method of treating such highly contaminated samples is to plot ^{230}Th/^{232}Th against ^{234}U/^{232}Th for each sample[6]. If these travertines had all formed at approximately the same time from mixtures of a homogenous, pure, chemically precipitated calcite, admixed with a single detrital component with a uniform ^{230}Th/^{232}Th ratio, then they should lie on a line with a slope equal to the ^{230}Th/^{234}U ratio of the chemically precipitated carbonate, and a ^{230}Th/^{232}Th intercept equal to the value for the detrital component today (or $e^{-\lambda_0 t}$ times the value of the initial ^{230}Th/^{232}Th ratio, where λ_0 = decay constant of ^{230}Th).

Figure 2 shows a graph of the analyses of the contaminated samples. They define a line with a slope of 0.5850 ± 0.0002; this taken together with the average ^{234}U/^{238}U ratios of the samples yields an apparent age of 99.4 ± 0.1 kyr. The error of this age estimate was evaluated by comparing regression lines through the points, taking each variable in turn as independent. Clearly the accuracy of such an age determination cannot be as great as implied by the variance of the regression line. No account has been taken of the errors of the individual analyses, and to some extent the accuracy of the age also depends on the validity of the assumptions given above, namely that all samples were mixtures of two uniform end-members (calcite and detritus). Until the validity of this method of collective age analysis has been established in a wider range of circumstances (see, for example, ref. 7) we cannot properly evaluate an error for the calculated age, although it is presumably comparable to the average error of the individual dated samples, about ±8%.

The initial ^{230}Th/^{232}Th ratio of 1.6 obtained from this regression analysis is close to the value commonly encountered in

Table 1 Radiometric data for samples from Tata travertine mound

Stratigraphic layer*	Level height from base (m)†	Sample no.	^{234}U/^{238}U	^{230}Th/^{234}U	^{230}Th/^{232}Th	Age (kyr)	[U] (p.p.m.)

§ Obtained by interpolation of samples 22, 23, 45; see text.

0028–0836/82/070590—02$01.00

detrital contaminants. In fact this is very close to the value of 1.5 which was used to obtain 'corrected' ages for the highly contaminated samples (Table 1). Nevertheless, at least one of those corrected dates (for sample 23) is still far from our new collective estimate for the age of the archaeological layer. This is because for samples with such low ^{230}Th/^{232}Th ratios the corrected age is very sensitive to the choice of initial ^{230}Th/^{232}Th ratios, while the value of that ratio in an individual sample may have differed significantly from the estimate obtained by regression from the complete set of samples. This discrepancy in ages emphasizes the value of the correlation method shown in Fig. 2 for obtaining a collective age.

The ^{234}U/^{238}U ratios of all the travertines analysed here are strikingly low. Correcting for the age of the deposit, they correspond to initial ratios of from 0.799 to 0.712, average = 0.738 ± 0.028. They are similar to the values obtained by Cherdyntsev at this site (0.80 ± 0.01), and indicate that the uranium in the spring water feeding the travertine deposits was derived from a source that was intensely leached, such as a deep soil profile. Such low ratios are rarely encountered in groundwaters or in carbonates precipitated from them.

The estimate of the age of the cultural layer obtained by the regression analysis lies midway between the ages of the over- and underlying layers and is consistent with a fairly constant rate of accumulation of travertine at between 0.007 and 0.018 cm yr^{-1}. The culture layer itself is described by Vértes[8] as having formed during a hiatus in the deposition of travertine, at least locally, and a period of relatively rapid deposition of aeolian detritus, first sand and then loessic silt.

This age estimate of the culture layer agrees well with the palaeontological estimates of palaeoclimate and thus of timing relative to glacial chronology. Kretzoi and Vértes[9] conclude that the site was occupied sometime after the thermal optimum of the last interglacial but considerably before the onset of the next glaciation. The climate at the site was estimated by them to have been "somewhat cooler and more continental then at present"; based on the associated mammalian fauna an average July temperature of 19 °C is estimated. These characteristics would be consistent with a point in the last interglacial when climate began to deteriorate in advance of an ensuing glacial stage such as isotope stage 5a, which occurred at about 90–100 kyr (ref. 10).

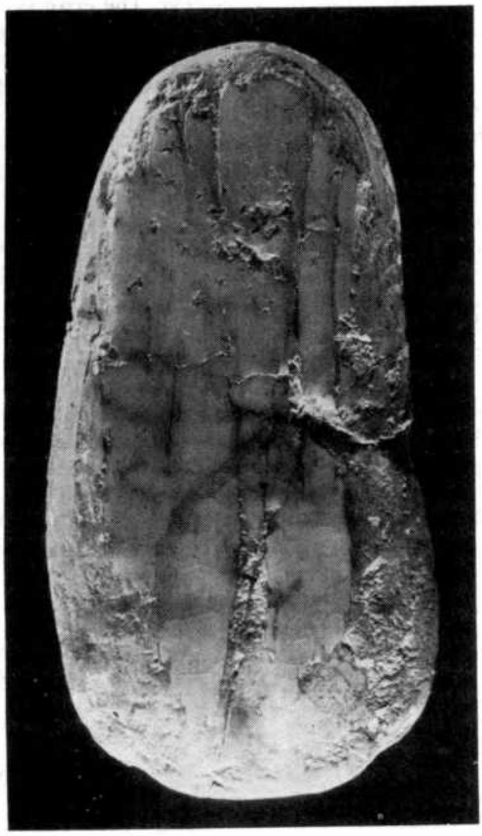

Fig. 1 Ivory plaque, made from piece of a mammoth's molar tooth, and rubbed with ochre (churinga). Photograph courtesy of A. Marshack. Plaque is 10.8 cm long.

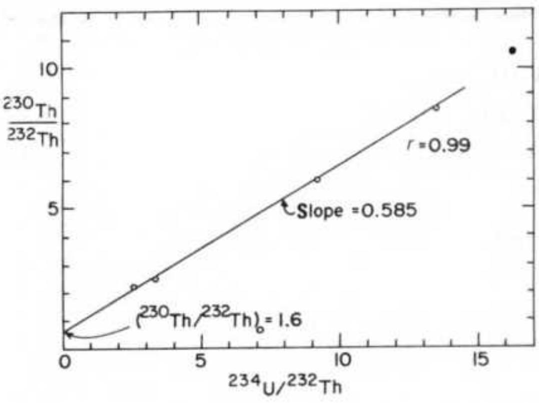

Fig. 2 Correlation between ^{230}Th/^{232}Th and ^{234}U/^{232}Th for radiometric analyses of contaminated travertines above and below the cultural layer of Tata. Slope of line gives estimate of ^{230}Th/^{234}U ratio of authigenic calcite component of travertine, from which age may be computed. Intercept gives ^{230}Th/^{232}Th ratio of detrital component.

We conclude that hominids who were utilizing a Mousterian tool assemblage occupied this site about 100 kyr BP., and created at least one purely decorative artefact. From what is known about the association between cultural remains and hominid skeletal remains at other Eastern European sites, we may infer that the makers of these artefacts were of the subspecies *H. s. neanderthalensis*. This is also consistent with our limited knowledge of timing of the appearance of *H. s. sapiens* and the disappearance of Neanderthal man. Eventually, through dating of other artefactual and hominid skeletal sites such as La Chaise[11] we hope to be able to reconstruct a complete chronology of the various stages in the cultural and biological evolution of the middle and upper Pleistocene.

This study was supported by funds from the National Geographic Society, the Social Sciences and Humanities Research Council of Canada and the Natural Sciences and Engineering Research Council of Canada. We thank A. Dixon and M. M. Russell for analytical assistance and A. Marshack for discussions on the nature of the decorative artefacts and for permission to use his photographs of them. McMaster Isotope and Nuclear Geochemical Contribution Number 124. This paper is dedicated to the memory of Dr Skoflek who died in an accident on 6 August 1981.

Proline content does not influence pest and disease susceptibility of barley

S. W. J. Bright*, P. J. Lea*, J. S. H. Kueh*, C. Woodcock†, D. W. Hollomon† & G. C. Scott†

Departments of *Biochemistry and †Insecticides and Fungicides,
Rothamsted Experimental Station, Harpenden,
Hertfordshire AL5 2JQ, UK

The genetic engineering of crop plants for specific desired characters is of potential importance in agriculture[1]. Serious consideration must therefore be given to undesirable side effects of particular modifications. The soluble nitrogen content of leaves is important in the relationship between plants and their insect predators and increases during periods of environmental stress[2,3]. Soluble proline increases markedly during water stress in a wide range of plant species including barley[4,5] and it has been suggested that plants selected for higher proline content may be more tolerant of drought stress[6]. However, proline is phagostimulatory to locusts when presented on an inert matrix[7] and this work has been extended by Haglund[8] to suggest that proline (or valine) may be a cue detected by grasshoppers to lead them to drought-stressed nitrogen-enriched plants. Plants selected for a higher content of free proline in an attempt to increase their tolerance of drought stress might therefore prove more attractive to insect predators. To test this hypothesis we have now compared the responses of locusts, slugs, aphids and a mildew fungus to normal barley and a barley mutant[9] which has up to six times the normal content of free proline in the leaves. We find no evidence that the mutant is more susceptible than its parent to damage by any of these organisms.

Unstressed leaves of the mutant R5201 were found to contain up to six times the soluble proline of the parent line in the first three leaves over a 16-day period (Table 1). We examined two aspects of pest attack: whether locusts or slugs would choose preferentially to attack and consume mutant plants and whether growth and reproduction of aphids or mildew were greater on the mutant than the wild type. All four organisms are economically important and include a major pest and an important disease of barley.

Locust plagues have been correlated with periods of environmental stress[3] and locusts might therefore be expected to detect the higher proline content of the mutant. Locusts from two separate genera (*Schistocerca gregaria* and *Locusta migratoria*) were allowed to feed for 48 h until ~50% of the shoot fresh weight had been consumed. Observation every 8 h of the order in which plants were attacked, and measurement of the weight of material eaten (Table 2) gave no evidence for preference of mutant over parent plants by either species of locust (differences not significant at $P < 0.05$).

Proline has been reported to be a feeding attractant for snails[10]. Slugs damage cereals either by attacking seeds or by shredding young leaves. We therefore examined the possibility that slugs could distinguish between the high proline mutant, its parent cultivar and a further cultivar, Bomi, included as an extra control. In this case (Table 3), although there was no significant preferential shredding of the leaves of R5201 compared with the parent, the slugs did not attack Bomi to the same extent as the other two lines.

Table 1 Proline content of the first three leaves of two lines of barley

Leaf no. from germination	Age (days)	Proline content (nmol per g fresh wt ± s.e.) Maris Mink	R5201
1	6	70±4	259±31*
	10	72±9	346±39*
	16	71±6	224±23*
2	10	79±8	493±69*
	16	73±6	207±11*
3	16	38±7	164±25*

Seeds of Maris Mink and R5201 were grown in Eff compost (Eff Products) in a controlled environment chamber (temperature 20°/16 °C, 16 h day, with light 11,000 lx from fluorescent plus tungsten light). On day 6, plants were transferred from seed trays to 4-inch pots (two per pot). Three samples each of three leaves were analysed. The entire leaf blade or that which had emerged from the sheath was taken. Leaves were ground in 3% w/v sulphosalicylic acid and assayed for proline content by the acid–ninhydrin method[9,17].

* Significant difference from Mink values at $P < 0.01$ by *t*-test.

Because aphids are vectors of virus diseases their control is of major importance in cereal farming[11]. Aphids are known to be able to detect some amino acids[12]. We therefore compared the multiplication rates of the cereal aphid (*Sitobion avenae*) on the three test lines of barley, and found that the aphids multiplied rapidly on all the lines tested (Table 4), and that there was no significant difference between the numbers of young on the leaves.

Powdery mildew (*Erysiphe graminis*) is also of considerable economic importance in British agriculture[11]. In a standard leaf bioassay, growth of mildew was the same on Maris Mink and R5201 3 days after inoculation (Table 4) and visual inspection at 14 days revealed no differences in disease development on any line.

A complicating factor in these experiments was that mutant plants were somewhat larger than controls (Table 2). It is unclear whether this is caused by a pleiotropic effect of the gene for proline accumulation, other mutated genes or a physiological difference in the seed samples used. Both water content[13] and plant age[14] can contribute to palatability of plant diets and might confound any effect of proline content. However, the absence of any observed preference for mutant or parent by the four tested organisms suggests that in this case these effects are small. These points can only be settled by reselection of mutant lines after backcrossing to normal types, a programme now being undertaken.

The use of a mutant with a single gene change leading to proline accumulation in a background substantially isogenic

Table 2 Preference of locusts for feeding on two lines of barley

Locust	Test plant	Fresh wt per plant (mg ± s.e.) Control	+ Locusts	Estimated consumption	Fraction consumed (% ± s.e.)
Schistocera gregaria	Maris Mink	292±7	120±15	172	59±5
	R5201	348±9	187±13	161	46±4 (NS)
Locusta migratoria	Maris Mink	173±7	100±12	73	42±7
	R5201	230±8	169±14	61	27±6 (NS)

Seeds were grown for 6–7 days as in Table 1, and 24 plants per treatment were transplanted to a 22 × 16 cm seed tray in a 2 × 2 Latin square. After a further 2 days' growth, the tray was placed at the bottom of a glass side cage 67 × 64 × 24 cm, fitted with a 100-W light bulb directly over the centre of the square. Mature adult locusts were purchased from Larujon locust suppliers, Colwyn Bay. Two male locusts were introduced into the cage and left for 24 h at 20 °C, when they were replaced with two female locusts for a further 24 h. The shoots were individually weighed after 48 h and compared with the weight of shoots in an identical tray in the absence of locusts. Essentially similar data were obtained in replicate experiments carried out with both locust types. NS, not significantly different from Maris Mink value at $P < 0.05$ by *t*-test.

Table 3 Susceptibility of three lines of barley to damage by slugs

Test plants	% Of plant shredded Expt no. 1	2	3	4	Grand mean ± s.e.
Maris Mink	40	60	50	38	47 ± 4.3
R5201	28	26	65	38	39 ± 6.1
Bomi	10	10	16	18	13 ± 1.6*

Seeds were grown in a glasshouse in rows of seven or eight plants in plastic trays with Eff compost. After 11 days 10 slugs (adult *Derocerus reticulatum*) that had been starved for 5 days were placed equidistant from the three rows. The trays were kept in a slug rearing room (12 h day 15 °C, night 5 °C) for 7 days. Two independent observers then estimated the percentage of plants that had been shredded. The values quoted are the means for the two observers in the four different experiments.

* Significantly different from other values at $P < 0.01$ by t-test.

Table 4 Growth and multiplication of aphids and mildew on three lines of barley

Organism	Test plant	Growth No. of young
Aphid	Maris Mink	17.5 ± 1.5
	R5201	18.1 ± 1.3
	Bomi	23.6 ± 3.2
		Colony length (μm ± s.e.)
Mildew	Maris Mink	112 ± 4
	R5021	121 ± 6
	Bomi	91 ± 5*

Seeds were grown in a glasshouse. For the growth of aphids, plants at 12 days were enclosed in a cylinder of dialysis tubing sealed at the top with cotton wool. Five adults or large nymphs of the cereal aphid (brown *Sitobion avenae*) were introduced onto each plant. After 7 days the number of young aphids was counted in 12 replicates of each test plant. Growth of barley powdery mildew (*Erysiphe graminis* f.sp *hordei* isolate 23D5) on intact 11-day plants was assessed using leaf segments removed 72 h after inoculation (1,000 conidia per cm^2). Segments were stained and cleared in trypan blue in lactophenol[18] and the length of at least 25 colonies measured.

* Significantly different from other values at $P < 0.01$ by t-test. All aphid values not significantly different at $P < 0.05$.

with the parent cultivar provides a strong, if limited, test of Haglund's hypothesis[8] that proline may be detected by grasshoppers to lead them to leaves enriched with nitrogen. The mutant, which accumulates proline within the leaf, has allowed us to test this hypothesis without external application of amino acid solutions, with its attendant disadvantages of plant or microbial degradation and dilution or run off during the test period. The third method of increasing internal proline by the application of water stress is also inferior because there may be associated increases in other nitrogenous compounds such as asparagine, glutamine and glycine betaine[4,15], and alterations in hormone levels[16]. Our experiments always showed greater differences between the two control barley varieties than between the mutant R5201 and its parental variety. Any possible differences are therefore small compared with acceptable varietal differences. Furthermore, the tests we have used are capable of discriminating between varieties and are therefore not biased to give a negative result. Our results therefore do not support the hypothesis that any of the tested organisms preferentially feed on, detect or multiply faster on barley plants with a sixfold increase in soluble proline. It thus seems unlikely that such increases in proline content will increase the risk of pest and disease development, so that we can now proceed to investigate the effects of leaf proline content on the ability to resist environmental stress.

We thank Mrs C. Lea for facilities for the locust experiments, Mr J. Franklin for growing the barley and Dr B. J. Miflin for helpful discussions.

Identification of a β-endorphin-like peptide in cultured human placental cells

Anthony S. Liotta, Richard Houghten & Dorothy T. Krieger

Department of Medicine, Mount Sinai School of Medicine,
New York City, New York 10029, USA

In the pituitary, adrenocorticotropic hormone (ACTH)- and β-endorphin-related peptides are post-translationally derived from a common precursor glycoprotein[1,2]. ACTH- and β-endorphin-like peptides have been demonstrated in human placental extracts by radioimmunoassay (RIA), bioassay and opioid radioreceptor assay[3–7]. Recently, we have shown that short-term cultured human placental trophoblastic cells synthesize a high molecular weight glycoprotein(s) physicochemically similar to the pituitary common precursor molecule; ACTH(9–15)- and β-endorphin(1–9)-like fragments were detected in a tryptic digest of this precursor. Pulse-chase experiments revealed that radiolabel disappeared from the molecule and accumulated in smaller molecular species having either ACTH or β-endorphin antigenic determinants[8]. We now report the use of reverse-phase HPLC to resolve the tryptic fragments of one component of β-endorphin-like peptide synthesized in placental cells, and show that it is comparable to synthetic human β-endorphin. The two reverse-phase HPLC systems used resolved all tryptic fragments of human β-endorphin (β_h-endorphin) with differing selectivities, thus providing two unique 'fingerprints', in analogy to conventional two-dimensional peptide analysis. The fact that identical maps were obtained for β_h-endorphin and the placental peptide in both systems, provides strong evidence that they are structurally identical.

Human term trophoblastic cells were prepared and maintained in tissue culture as previously described[8]. On day 3 of culture, cells were incubated for 6 h in the presence of ^3H-lysine (SA, 112 Ci $mmol^{-1}$; 100 μM). Cells were homogenized in 0.2 M HCl/1 M formic acid containing 10 mM dithiothreitol (DTT), centrifuged (18,000g at 10 °C for 30 min) and the supernatant submitted to molecular sieve chromatography[8]. Material that eluted with a K_{av} similar to β_h-endorphin was pooled and lyophilized. After reconstitution, the sample was applied to a microcolumn packed with affinity-purified anti-β-endorphin antiserum covalently linked to Sepharose 4B[8]. The anti-β-endorphin immunoglobulin recognizes determinants within the β-endorphin(20–28) sequence and reacts with β_h-lipotropin on a nearly equimolar basis, while not reacting at all with human (h)ACTH(1–39). Specifically retained material was eluted with 25 μg synthetic β_h-endorphin dissolved in 500 μl 10 mM Tris-HCl pH 7.5, containing 10 mM DTT and 0.01% bovine serum albumin (BSA)[8,9]. The eluate was diluted with 1.25 ml 0.05 M HCl/2 M CH_3COOH and subjected to cation-exchange chromatography[10]. The elution position of the synthetic β-endorphin was located by β-endorphin RIA[10].

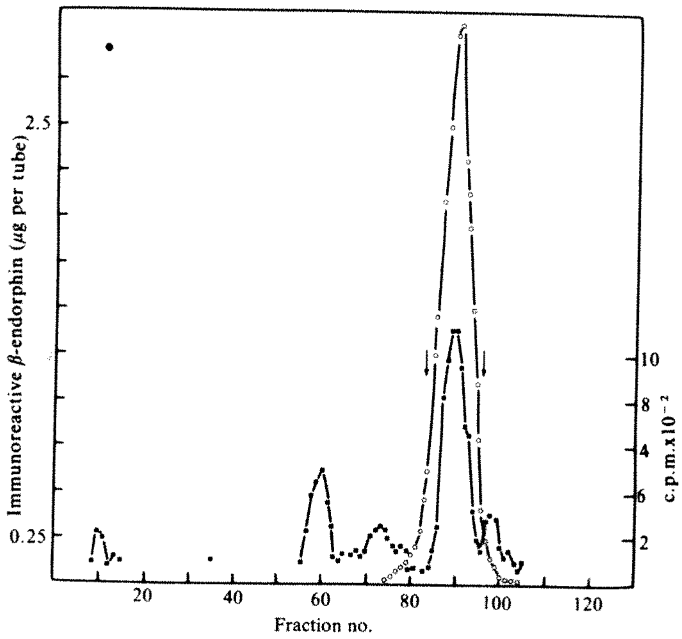

Fig. 1 Cation-exchange chromatography of the immune affinity-purified placental β-endorphin-like material. After incubation of placental cells with ^{3}H-lysine, an extract was prepared and chromatographed on a Sephadex G-50 superfine column (1 × 60 cm; eluent, 0.2 M HCl/1 M formic acid, containing 0.01% human serum albumin; flow rate 10 ml h^{-1}). Material eluting with a K_{av} similar to authentic β_h-endorphin was pooled, lyophilized, and further purified by immune affinity chromatography (see text). ^{3}H-labelled immunoreactive β-endorphin was eluted with 25 μg synthetic β_h-endorphin. The eluate was applied to a 0.9 × 15 cm SP-Sephadex C-25 column equilibrated with 5 mM HCl/1.8 M CH_3COOH. Elution was performed with a linear gradient of NaCl (0.5 M NaCl achieved after 100 1-ml fractions were collected). All fractions were assayed in the β-endorphin radioimmunoassay to locate the synthetic β_h-endorphin peak (○) and aliquots (100 μl) of fractions were removed for liquid scintillation counting (■; activity <10 c.p.m. above background, not plotted). Fractions containing most of the synthetic β_h-endorphin (fractions 83–96, defined by vertical arrows) were pooled for reverse-phase HPLC (see Fig. 2). As the purpose of this study was to determine if any of the ^{3}H-labelled β-endorphin-like material was physicochemically similar to β_h-endorphin, the remaining fractions were stored for future analysis.

Aliquots of the appropriate fractions were removed for liquid scintillation counting and the remaining portions pooled and analysed by reverse-phase HPLC using the triethylammonium phosphate/CH_3CN solvent system of Rivier[11]. About 9.3 × 10^7 d.p.m. per mg protein was incorporated into trichloroacetic acid-precipitable protein; an average of 6.12 × 10^3 d.p.m. per mg protein of β-endorphin-like material was specifically eluted from the immune-affinity microcolumn. Cation-exchange chromatography revealed that ~47% of this ^{3}H-labelled material co-eluted with synthetic β_h-endorphin (Fig. 1) and ~88% of this ^{3}H-labelled material showed a retention time identical to that of synthetic β-endorphin after reverse-phase HPLC (Fig. 2). Of the synthetic β_h-endorphin added to the placental sample at the affinity column elution step, 91% was recovered after reverse-phase HPLC. We do not attribute any physiological significance to either the absolute amount of ^{3}H incorporated into β-endorphin-like material or the relative amount compared to TCA-precipitable ^{3}H-labelled products, as different tissue culture conditions significantly alter biosynthetic capacity of the tissues. In addition, we do not know how much *in vitro* synthesized β-endorphin-related material was released into the medium during the labelling procedure.

The HPLC-purified sample was then trypsinized and the digest analysed by reverse-phase HPLC in two different chromatographic conditions (see Fig. 3 for details). Five major UV-absorbing peptide peaks were detectable in each system, indicating the positions of the fragments generated from the synthetic β-endorphin. β-Endorphin contains five lysyl residues (but no arginine residues) at positions 9, 19, 24, 28 and 29; the Lys^{29}-Gly^{30} bond was not significantly cleaved in the conditions used. Hence all tryptic fragments of β_h-endorphin contain a lysyl residue, and all tryptic fragments of the placental peptide should be ^{3}H-labelled if the placental peptide is structurally identical to β_h-endorphin. Five major ^{3}H-labelled peaks exhibiting the same retention times as the synthetic fragments were indeed detected in both systems (Fig. 3). Further evidence for the identity of the ^{3}H-labelled fragments with the synthetic tryptic peptides was obtained by exopeptidase digestion studies. In all cases, ^{3}H-lysine was released in conditions that released lysine from the synthetic fragment. Carboxypeptidase B digestion rapidly released ^{3}H-lysine from the ^{3}H-labelled β-endorphin(1–9)-, (10–19)-, (20–24)- and (25–28)-like moieties. The ^{3}H-labelled β-endorphin(29–31)-like fragment was completely resistant to carboxypeptidase B action; aminopeptidase M, however, did release ^{3}H-lysine (lysine is located at the N terminus of authentic β-endorphin(29–31)). Lysine was identified by the pre-column *o*-phthaldialdehyde derivatization/reverse-phase HPLC system described by Jones *et al.*[12] (data not shown).

In contrast to these findings, Julliard *et al.*[13] recently reported that high molecular weight precursor β-endorphin-like material in extracts of human placenta is a fragment of IgG. Using a commercially prepared extract derived from whole-term placentae and sequestered postpartum blood (placentae are used solely as a source of blood; an average of 24 g haemoglobin is extractable per placenta, indicating ~200 ml of blood per placenta)[14,15] and a purification procedure which included an

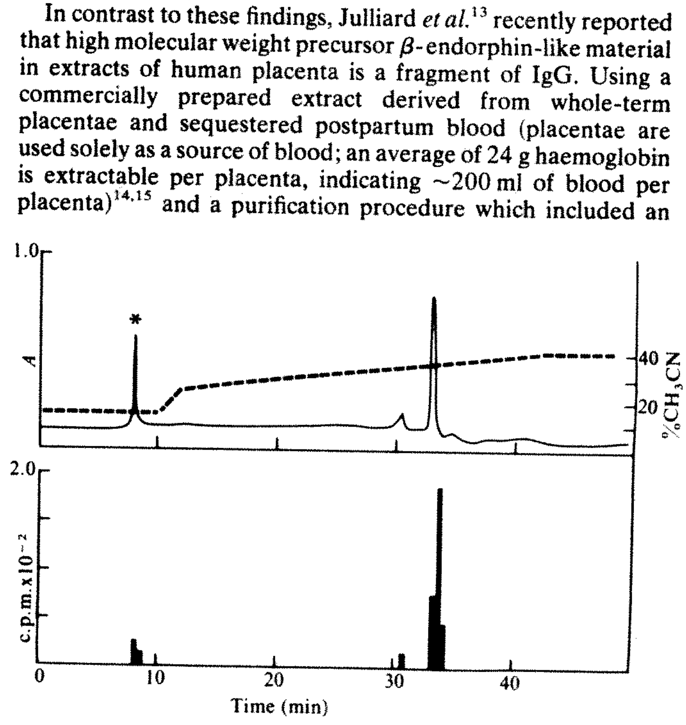

Fig. 2 Reverse-phase HPLC of synthetic β-endorphin and co-eluted ^{3}H-labelled immunoreactive β-endorphin resolved by cation-exchange chromatography (see Fig. 1). Fractions were pooled, desalted on a Sep-Pak C18 cartridge (Waters Associates)[10] (99% recovery of immunoassayable β-endorphin; 91% recovery of ^{3}H-labelled material) and analysed by reverse-phase HPLC (Ultrasphere ODS column, 0.46 × 25 cm) using the triethylammonium solvent system described by Rivier[11] (solvent A, 0.12 M H_3PO_4, adjusted to pH 3.0 with triethylamine; solvent B, H_3PO_4/triethylamine containing 70% acetonitrile). Flow rate was 0.5 ml min^{-1}; the CH_3CN gradient is indicated by the broken line. Upper panel, synthetic β-endorphin peak was detected by UV absorbance at 210 nm (continuous trace, 1.0 absorbance units full scale (AUFS)); the appropriate fractions were also assayed by β-endorphin RIA to confirm the elution position and calculate recovery (data not shown). Lower panel, aliquots (50 μl) were removed for liquid scintillation counting (see Fig. 3 for counting details). Peak marked by * on the UV trace represents an injection artefact. A small peak (upper and lower panels) is detected eluting with the retention time of the Met(O) form of β_h-endorphin. The nature of the ^{3}H-labelled peak eluting at 8.5 min is unknown. Material detected by UV monitor reached the fraction collector 0.72 min after passing through flow cell; data shown are not corrected for this difference.

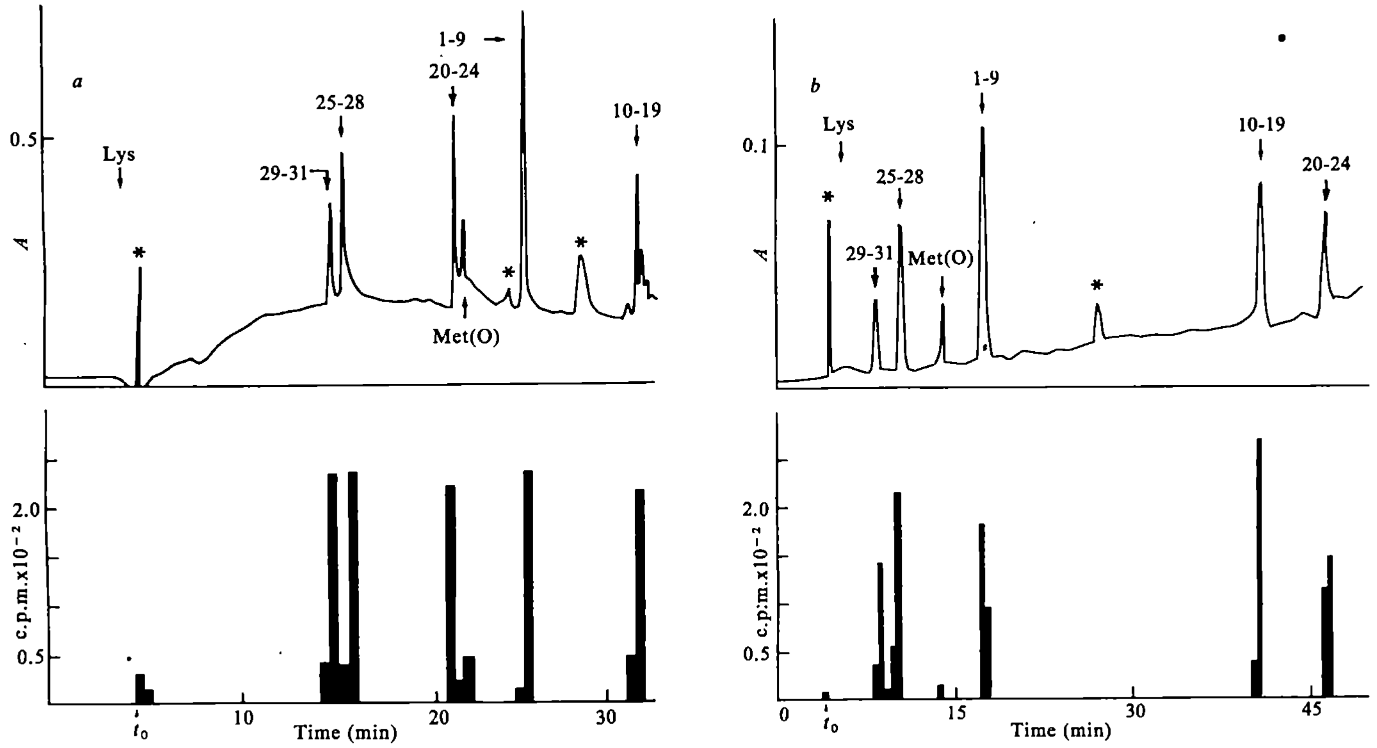

Fig. 3 Comparative HPLC tryptic peptide maps of synthetic humanβ-endorphin and purified ^{3}H-labelled placental β-endorphin-like peptide. Fractions containing the HPLC-purified placental peptide (see Fig. 2) were pooled and concentrated on a Sep-Pak C18 cartridge (Waters Associates). The cartridge was washed to remove H_3PO_4 and salts, and the retained peptides were eluted with 80% CH_3CN in 0.01 M HCl. The CH_3CN was removed with a gentle stream of N_2 and the aqueous phase lyophilized. The sample was then reconstituted in a minimum volume of 2 M DTT, incubated at 60 °C for 8 h (to reduce any Met(O) or Met(O_2) forms present) and trypsinized (25 °C for 8 h; tosylphenylethylchloromethylketone (TPCK)–trypsin to protein weight ratio of 1:1,000, *p*H 7.5). The sample was diluted to 525 µl with 0.01 M trifluoroacetic acid (TFA) and equal aliquots (250 µl) analysed in two separate gradient reverse-phase HPLC systems. *a*, Altex ultrasphere ODS column (0.46 × 25 cm, 5 µm) was equilibrated with 0.01 M TFA (Bennett *et al.*[16] have suggested the use of perfluorinated carboxylic acids for reverse-phase HPLC of peptides) containing 4% CH_3CN and the sample was injected onto the column using a 250 µl Altex sample loop. Elution was performed for 2 min at 4% CH_3CN/0.01 M TFA, followed by a 25-min linear gradient of 4–64% CH_3CN in 0.01 M TFA. Flow rate was 0.5 ml min^{-1} and 0.25 ml fractions were collected. Column effluent was continuously monitored at 210 nm (0.5 AUFS). *b*, Lichrosorb RP-18 column (0.46 × 25 cm, 10 µm) was equilibrated with 2% isopropanol in 0.015 M ammonium acetate, *p*H 4.1). Elution was performed for 5 min with the equilibration buffer, followed by a 45-min linear gradient of 2–50% isopropanol in 0.015 M ammonium acetate. Column effluent was continuously monitored at 220 nm (0.1 AUFS). All samples were evaporated in counting vials, dissolved in 200 µl 0.02% SDS, and then 15 ml Aquasol-2 was added to each vial before liquid scintillation counting. Arrows indicate the elution positions of synthetic β_h-endorphin(1–9), (10–19), (20–24), (25–28) and (29–31). These marker peptides were obtained by trypsinization of synthetic β_h-endorphin and identified by amino acid analysis of the resolved fragments. In addition, the elution position of lysine and the methionine sulphoxide [Met(O)] form of β-endorphin(1–9) are shown. Peaks marked by * on the UV trace are inherent to the baseline trace and not components of the peptide profile. The nature of the small radioactive peaks eluting at the retention time of a completely unretained compound (t_0) is unknown. Upper panels, UV absorbance profiles; lower panels, ^{3}H-labelled profiles. Material arrived at the fraction collector 0.72 min after passing though the UV monitor flow cell; the comparative maps shown are corrected for this time factor.

immune-affinity chromatographic step (that is, Sepharose-immobilized anti-β-endorphin antiserum), they isolated 269 mg of a glycoprotein (molecular weight (M_r) = 48,500) that contained the antigenic determinants of both ACTH and β-endorphin. Structural analysis demonstrated this protein to be the heavy chain of the IgG1 class. The protein cross-reacted 0.039% and 0.0064% (by weight), respectively, with the specific β-endorphin and ACTH antisera used. Inspection of the IgG1 heavy chain revealed that sequences 364–377 and 9–22 had 40% and 36% homologies, respectively, with the antigenic determinants of β-endorphin and ACTH. We believe these results can be reconciled with our findings by considering the starting material used in the previous study, that is, the precipitate formed when whole-term placentae and entrapped blood are frozen, thawed, homogenized in 0.9% NaCl and brought to 25% ethanol. Such an homogenate exhibits a broad range of proteolytic activities. We have been unable to recover significant amounts either of highly purified rat pituitary precursor ACTH/β-endorphin, synthetic β_h-endorphin, or hACTH(1–39) when we added these to a similarly prepared placental homogenate (~25 pmol of each added per placenta). In addition, as Julliard *et al.*[13] performed an affinity chromatographic purification step, using anti-β-endorphin antiserum coupled to Sepharose, any authentic precursor ACTH/β-endorphin material present would have had to compete with a very large molar excess of the IgG1 heavy chain (haemoglobin and β- and γ-globulins comprise most of the proteins precipitated at 25% ethanol) for column binding sites, and hence, even if bound, would comprise a minor component.

Our results further demonstrate synthesis in cultured human placental cells of a peptide that is structurally similar to human pituitary β-endorphin. Moreover, these data, together with previous results[8], suggest that, analogous to the pituitary, the placental β-endorphin-like moiety is contained within a larger precursor molecule and is derived from it by post-translational proteolytic cleavage.

Averaged evoked responses and psychometric intelligence

S. F. Blinkhorn* & D. E. Hendrickson†

* Psychology Department, Hatfield Polytechnic, PO Box 109, Hatfield AL10 9AB, Hertfordshire, UK
† Psychology Department, Institute of Psychiatry, DeCrespigny Park, London SE5 8AF, UK

Attempts to establish correlations between psychometrically defined and measured intelligence and brain electrical activity have met with limited success. For example, as in the work of Ertl[1], the latency of components of averaged evoked potentials (a.e.ps) has been adopted as the EEG measure most likely to correspond to intelligence quotient (IQ). Although correlations as high as 0.35 have been reported on samples unselected for IQ, the sign of the correlation seems to depend on the stimulus modality used, which suggests that a straightforward identification of intelligence with 'mental speed', for which read 'short a.e.p. component latencies', is inappropriate. Hendrickson and Hendrickson[2] have proposed both a novel a.e.p. measure and a theory to account for individual differences in scores based on this measure, claiming remarkably high correlations with IQ, of the order of 0.7–0.8. We report here a study using highly selected subjects which supports these claims.

The Hendricksons' theory[2] proposes that higher intelligence is a function of low error rates in the central nervous system and that as a result of the way in which information is coded and transmitted in the brain, the effect of error is to reduce both the number and amplitude of excursions of the a.e.p. trace. Therefore, differences in IQ should be manifested in a.e.p. traces as differences in complexity, which can be determined simply by measuring the length of the trace over a standard epoch. This measure we refer to as the 'string' measure, as in effect one treats an a.e.p. trace like a piece of string and measures its straightened length.

The principal psychometric measure used was Raven's Advanced Progressive Matrices (APM) 1962 edition, a test with a substantial reputation as a culture-reduced measure of general intelligence with low achievement loading, routinely used in the selection of psychology undergraduates at the Hatfield Polytechnic, UK. Test scores had been obtained previously and were unknown to D.E.H. who analysed the EEG recordings made.

Thirty-six subjects were tested initially. Of these, three were not used in further experiments because of technical problems with their EEG records. Of those remaining, 17 were male and 16 female, with an age range of 18–36 yr. (All subjects were or had been undergraduate psychology students at the Hatfield Polytechnic.) Subjects scored between 17 and 35 on the APM (mean score ±s.d. = 26.03±4.33). The APM manual gives the estimated mean and standard deviation for university students as 21 and 4.0 respectively, and for adult students 'of more than average intellectual capacity' as 10.06 and 8.95 at a first testing and 13.95 and 9.38 on re-testing. (These values take into account the changes between the 1947 and 1962 editions). Furthermore, in the table of estimated norms, the 95th percentile point is given as 23–24 for 20–30-yr olds. In the absence of a more detailed calibration of APM scores in IQ terms, these and other indications in the manual suggest that the mean score in the group being studied corresponds to an IQ of ~128–130, with a standard deviation of between 5 and 7.5.

EEG recordings were carried out with the subject seated in a comfortable chair in a darkened, sound-attenuated room. Silver/silver chloride electrodes were attached using collodion to the scalp at the vertex and both mastoids. The subject was presented with a train of 100 tones through stereophonic headphones and asked to relax, listen to the tones and keep his eyes closed throughout the presentation. The background EEG was recorded from a bipolar derivation with the active electrode at the vertex and the reference electrode at the left mastoid. The output of the electrodes was amplified 10,000 times with virtually no high-frequency attenuation using a portable PTT4 EEG amplifier. Background EEG was recorded on one channel of a Yasec CD 1000 instrumentation tape recorder with stimulus markers recorded on a second channel for later analysis of the stimulus-initiated EEG activity. Auditory stimuli consisted of 1,000-Hz tones, 30 ms in duration, switched at the zero-crossing point (to minimize harmonic content) and presented binaurally at 85 dB. The inter-stimulus interval was randomly selected and varied between 1 and 8 s. The tone was generated and timed by a custom-built stimulus generator.

A PDP11/04 was used to average the post-stimulus 512 ms epochs from analog tape in the first instance. Three averaging passes were made: the first using 90 unselected epochs; the second, 64 epochs with eye movement and other obvious artefacts removed; and a third pass of 32 epochs. There were two records which had fewer than 64 'good' epochs because of recording difficulties, but all had at least 32. Variance was calculated for each of the three averaging passes. The process of averaging involved digitizing each 512-ms epoch at 1,024 points, thus the averaged waveform was based on 0.5 ms resolution.

Subsequently, as a control, unstimulated EEG was averaged. Specifically, the 256 ms immediately before stimulus onset were averaged for 90 unselected epochs, and 256-ms post-stimulus epochs were also averaged for comparison. As the shortest inter-stimulus interval used was 1 s, a 256-ms epoch was adopted for this control analysis to avoid residual evoked activity which might have contaminated 512-ms unstimulated string calculations. Mean unstimulated string score was 184.4±50.7 (±s.d). Mean string score over 90 post-stimulus 256-ms epochs was 278.2±133.4 (±s.d.). Units are arbitrary, but constant. The correlation between unstimulated string and APM was 0.127, which is not significantly different from zero. However, the correlation between post-stimulus 256-ms string and APM was 0.538, which is significantly different from zero at the $P<0.001$ level. The three original 512-ms string measures gave correlation coefficients of 0.530, 0.362 and 0.452 with APM for 90, 64 and 32 epoch passes, respectively, with significance levels of $P<0.001$, 0.02 and 0.005. None of the variance measures from the various data passes correlated significantly with APM. The highest scoring subject on the APM (35 correct out of 36) also had the highest scores for both the 90-epoch post-stimulus string measures, although the unstimulated string was unremarkable. Reducing these scores to those of the next highest scorer on the 256- and 512-ms 90-epoch string measures reduced the correlations between these and APM to 0.499 and 0.530, respectively.

In considering these correlations, it should be borne in mind that the various post-stimulus string measures were derived from repeated passes over the same data and not from independent observations. Thus, the correlations should be considered as different estimates of the same underlying correlation, and not as replications.

For 25 of the subjects in this study, scores in various other psychometric tests had been recorded previously. These were all verbal tests, and thus may be expected to be considerably more achievement-loaded than the APM. They included NIIP GT90A, a high-speed, conventional verbal measure; Verbal Concepts and Verbal Critical Reasoning, two tests developed for closed circulation emphasizing, respectively, verbal analogies and detection of fallacies; and various so-called 'divergent thinking' tests—uses of objects, meanings of words, etc. None of these tests correlated significantly with any of the EEG measures.

The principal feature of these results, therefore, is that despite the severe restriction of range on the IQ measure adopted, EEG–IQ correlations were at least as large as those found by other investigators using unselected subjects. This implies that

0028-0836/82/070596—02$01.00

over the full range of IQ the correlation would be substantially higher. Taking a value of 0.45 as a mid-range estimate from the various string–APM correlations, a s.d. of 7.5 or 5.0 IQ points for this sample would give a corrected correlation of 0.71 or 0.84, respectively.

Given the relatively small sample size, it is pointless to attempt great accuracy in estimating the underlying correlation between the string measure and IQ. However, unless the 'normal' data in the APM manual are substantially inaccurate or out of date, the data presented here suggest a correlation approaching the reliabilities typical of group tests of intelligence.

Correlations of this magnitude between measures which apparently have little in common are very rare. On the one hand psychometric tests involve the individual in problem-solving activities of a kind which might be thought amenable to the sort of analysis undertaken by cognitive psychologists. On the other hand, the string measurement procedure involves the subject in no decisions, makes no apparent demands on memory, involves no difficult perceptual discriminations, and uses stimulus intensities much greater than threshold. In this respect it differs from the procedure of Nettelbeck and Lally[3]. Furthermore, the effect obviously occurs in the first 256 ms after presentation of the stimulus, in a task which can perhaps best be described as mindless.

These results, and comparable results reported elsewhere[4] using similar techniques on a large sample of school children, suggest the possibility of identifying sources of individual differences in measured intelligence distinct from the quality of cognitive strategies and processes involved in intelligent performance, which might ultimately resolve several of the outstanding issues in differential psychology.

Motilin in the Purkinje cell of the cerebellum

Gajanan Nilaver*, Richard Defendini*, Earl A. Zimmerman*, Margery C. Beinfeld† & Thomas L. O'Donohue‡

None of the brain peptides has been demonstrated to be present in significant amounts in the cerebellum[1,2]. The only effector substance known in the Purkinje cell, whose axon carries the integrated output of the cerebellar cortex, is the decarboxylated residue of glutamic acid[3–6]. An antiserum raised against synthetic porcine gut motilin and directed at the midportion and carboxyl end of the 22-amino acid polypeptide[7] shows, in anatomically intact rat, mouse and human cerebellum, that most Purkinje cells contain motilin or a closely related substance[8]. We report here that motilin-absorbable immunoreactivity is evident from the spines of tertiary dendrites, through the cell body and axon, to nerve endings terminating, as expected, in the deep cerebellar nuclei and, unexpectedly, on nerve cells of some brain stem nuclei. In addition to its obvious functional implications, motilin is thus an important marker with which to re-examine the organization and projections of Purkinje cells, their ontogeny and their response to injury.

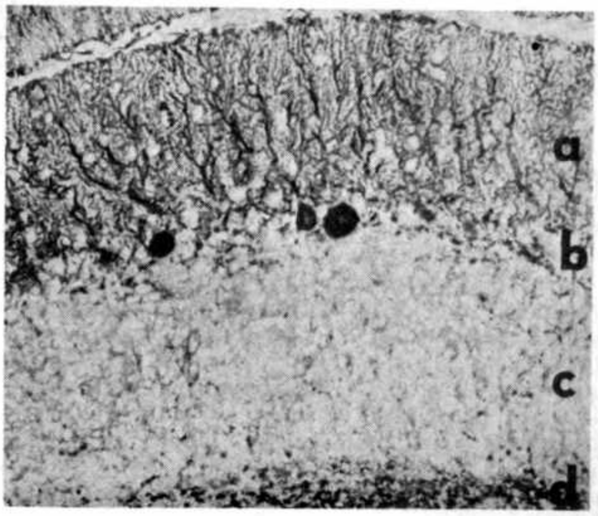

Fig. 1 Flocculus of rat cerebellum showing motilin immunoreactivity in dendritic tree of Purkinje cells in the molecular layer (a); three Purkinje cell bodies in the Purkinje layer (b); occasional beaded axons coursing through the granule cell layer (c); and gathering axons in the subcortical white matter (d).

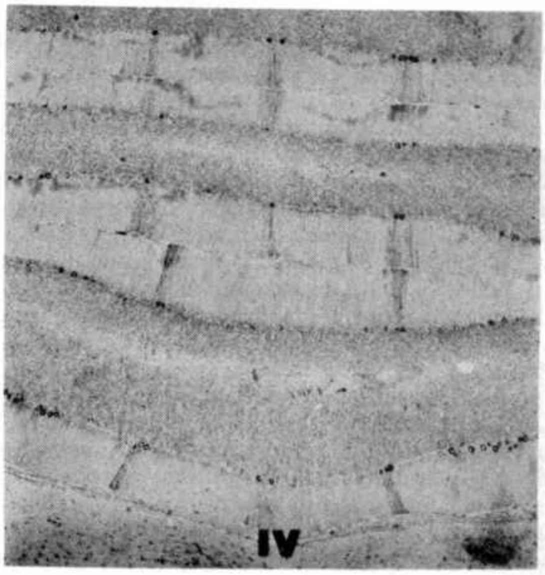

Fig. 2 Coronal section of rat cerebellar vermis and subjacent medulla. The symmetry of motilin-immunoreactive Purkinje cells and their dendrites between (1) the right and left sides, (2) opposite sides of the same folium, and (3) opposite surfaces of adjacent folia produces a palisading effect. (The pattern is best appreciated in sections, such as this one, in which < 50% of cells are reactive.) IV, Fourth ventricle, midline.

We examined the brains of 10 Long Evans rats and 10 Swiss albino mice, and the cerebellum of five human adults. Four of the rats were injected with 60 μg of colchicine in the lateral ventricle 48 h before killing. Animals were killed under pentobarbital anaesthesia by cardiac perfusion with isotonic saline, then 10% buffered formalin; brain fixation was completed by immersion in formalin overnight. Blocks of human cerebellum dissected at autopsy were fixed by immersion in 10% formalin for 48 h. The blocks were embedded in paraffin[9], and 6 μm serial sections were cut in the coronal or sagittal plane.

Rabbit anti-motilin antiserum was generated against synthetic porcine gut motilin conjugated to bovine thyroglobulin by the glutaraldehyde method[10] after multiple intradermal injection[11] of 500 μg of the immunogen emulsified in 1 ml of complete Freund's adjuvant and, 3 and 6 weeks later, further administration by the same route of 100 and 50 μg of the immunogen in incomplete adjuvant.

Immunocytochemistry was carried out by the indirect peroxidase method of Sternberger[12]. Deparaffinized tissue sections were reacted in sequence with the antiserum to motilin (1:800) at 4 °C overnight, goat anti-rabbit globulin (1:100) at room temperature for 30 min and rabbit peroxidase–antiperoxidase complex (1:400) at room temperature for 60 min. Reaction products were visualized with 3,3′-diaminobenzidine tetrahydrochloride[9]. Negative specificity controls included replacement of the primary antiserum with the rabbit's pre-immune serum and solid-phase preabsorption of the primary antiserum with 200 μg of synthetic porcine motilin bound covalently to cyanogen bromide-activated Sepharose beads[13].

The following forebrain structures were motilin immunoreactive in the rat and mouse: (1) clusters of pituitary cells in the pars distalis and, in the rat, also the pars intermedia; (2) a few nerve cell perikarya in the ventrolateral hypothalamus; (3) a few nerve cell bodies in the arcuate nucleus of rat only after colchicine treatment; and (4) bundles of fibres confined to the zona externa in the lateral recesses of the median eminence. None of the hypophysial or hypothalamic reaction products was seen after incubation of the primary antiserum with synthetic motilin.

The high concentration of motilin found in the cerebellum by radioimmunoassay of homogenized tissue extracts[7] is readily explained by the presence of immunoreactive products in most Purkinje cells, which often fill the soma of the cell, its dendritic arbor as far as the spiny tertiary branches, the length of its axon through the internal granule cell layer and white matter (Fig. 1), and its terminals on nerve cell bodies of the deep cerebellar nuclei Fig. 3. The other types of nerve cell in the molecular and granular layers of the cortex, as well as the nerve cells of the deep cerebellar nuclei themselves, are not reactive. In the rodent species examined, 90% of Purkinje somata in the hemispheres and the flocculus were labelled, whereas only one-half were reactive in the vermis. In the human vermis, the proportion of labelled Purkinje cells was much greater than in the rodents. Colchicine pretreatment in the rat intensified somatic staining, but did not alter the proportion of reactive cells.

In the rodent vermis, short and long runs of motilin-reactive Purkinje neurones alternate with runs of unreactive ones. The grouping is not random, as reactive groups often occupy the same position on either side of a folium and in adjacent folia (Fig. 2). The symmetrical palisades of reactive cells are continuous in serial sections in the coronal plane, running rostrocaudally in the sagittal plane. This pattern, which is analogous to the longitudinal organization of cortical efferents and afferents described by Voogd[14], suggests that the substance detected is intimately related to the functional organization of the Purkinje cell system.

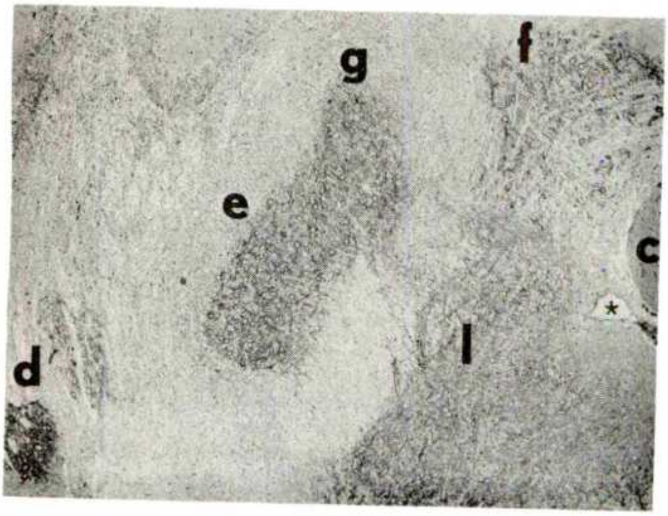

Fig. 3 Rat cerebellum. Numerous nerve cells in dentate (d), emboliform (e), globose (g) and fastigial (f) nuclei are outlined by motilin-immunoreactive axons and nerve terminals. The lateral vestibular nucleus (l) is also innervated. Fourth ventricle (★); vermal cortex (c).

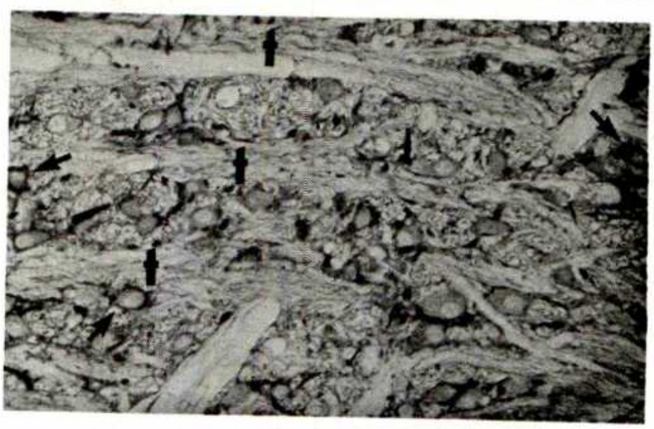

Fig. 4 Rat basis pontis. The bands of nerve cells lie between bundles (t) of transverse pontine (pontocerebellar) fibres. Several nerve cells are outlined by motilin-immunoreactive nerve terminals (arrows).

Most nerve cell bodies in the rodent cerebellar nuclei were surrounded by punctate immunoreactive products (Fig. 3) interpreted as axon terminals making synaptic contact with the cells. The vestibular nuclei presented a similar pattern. In addition, nerve cells in several other brain stem nuclei (spinal and motor fifth, basis pontis, medial parabrachial, dorsal tegmental, reticular gigantocellular, accessory superior olive, trapezoid, facial, prepositus, abducens and lateral lemniscus) were surrounded by motilin-absorbable immunoreactive terminals. As we found no reactive cells or axons in the brain stem, spinal cord, or dorsal root ganglia, the reactive terminals in these brain stem nuclei raise the possibility of previously unknown direct projections to the brain stem from the cerebellar cortex. Preliminary results of unilateral cerebellar leukotomy between the cortex and deep nuclei demonstrated a substantial diminution of reactive terminals in the brain stem, predominantly on the same side. Innervation of the nucleus basis pontis (Fig. 4), the precerebellar relay nucleus in the multi-station circuit between the cerebellar and cerebral cortices, suggests feedback modulation from the terminal Purkinje cell to its afferent station in the pons.

Electrophysiological studies of motilin report an excitatory effect in cerebral cortex[15]. The cellular distribution of motilin in the cerebellum described here supports a neurotransmitter role. Differential immunohistological studies in progress are expected to elucidate the relative distribution of motilin and γ-aminobutyric acid in the Purkinje cell population. Motilin immunoreactivity as a marker of Purkinje cell processes and nerve terminals, in conjunction with ablation, tracer, and radiolabel uptake experiments, provides a major new tool to study the organization of the cerebellar cortex.

Closure of membrane channels gated by glutamate receptors may be a two-step process

Measurements of currents through individual receptor-gated ion channels using the patch clamp technique have shown that each open channel contributes a square pulse of current and has a constant conductance, and that transitions between open and closed states are rapid[1]. To increase the signal-to-noise ratio of patch clamp recordings of glutamate channels in locust muscle, the bandwidth of the patch clamp amplifier has usually been restricted by a low pass filter (3 dB point, nominally 1 kHz with an 18 dB per octave slope). With concentrations of L-glutamate $\leq 5\times10^{-5}$ M, we previously found that frequency histograms of channel lifetimes, constructed from data recorded with a 1 kHz bandwidth, could be fitted by single exponentials using the least-squares method[2,3]. Mean channel lifetimes estimated from the exponentials agree reasonably well with values obtained by 'noise' analysis of locust neuromuscular junctions[4] and with mean values calculated directly by averaging the open times of single channel events[5]. However, the histograms are deficient in the region 0–1 ms because of the limited high-frequency response of the recording system. We have now recorded glutamate-gated channels in locust muscle membrane with signal-to-noise ratios of 3 : 1 or better and a recording bandwidth of d.c. to 10 kHz, and report lifetimes as brief as 50 µs. Frequency distribution histograms constructed from data recorded at 10 kHz suggest that the lifetime of the glutamate channel in extrajunctional membrane of locust muscle is governed by at least two exponential time-dependent processes, one of which has the effect of delaying channel closure.

Experiments were performed on the extrajunctional membrane of innervated extensor tibiae muscles from the metathoracic legs of adult (female) locusts (*Locusta migratoria* and *Schistocerca gregaria*) pretreated with concanavalin A (Con A) to block receptor desensitization[6]. The outsides of Pyrex (borosilicate) patch electrodes were coated with a film of nitrate cellulose dope before being filled with saline containing either glutamate or agonist. Recordings with clear signal resolution (signal-to-noise >3:1) are best obtained with a 10 kHz amplifier if the patch electrode seal resistance is >20 MΩ and the muscle fibre membrane is clamped[7] at potentials (such as −125 mV) more negative than the resting potential (about −60 mV). At −125 mV single channel currents often exceed 18 pA (Fig. 1).

The activity of single glutamate channels was recorded on a FM tape recorder with a bandwidth of >10 kHz for later analysis. To increase the objectivity of our measurements we have automated our measuring procedures. Recorded analog data are played back through a window comparator which produces a square pulse having a duration equal to the channel open time. The analog input signal and the upper and lower window levels are multiplexed and can, therefore, be displayed on the same beam of an oscilloscope, allowing the comparator levels to be easily adjusted. The input signal must fall through the window, that is the input signal must first cross the upper comparator level and then cross the lower level to initiate the digital output pulse. To terminate this pulse the input signal must rise above the window by crossing both comparator levels. (Crossings of only one comparator level are, therefore, ignored.) The duration of the square pulse (open time) and the intervals between square pulses (closed times) are then measured by a PDP11/34A computer. To validate this method the same channels were measured by hand and using the window comparator. The results obtained using the two methods showed very close agreement (>99%).

Three calibration techniques have been used to define the resolution of our system for recording and measuring single channel data. (1) Square current pulses, with rise and fall times of <1 µs, mixed with bandwidth limited noise, were injected into the front end of the patch amplifier. The noise and pulse amplitudes were adjusted to match channel data recorded using this amplifier and then analysed in the same way as comparable channel data. (2) Square voltage pulses, also with rise and fall times <1 µs, were injected into the bath containing the locust nerve–muscle preparation through a saline-filled microelectrode placed close to a patch electrode sealed onto the extrajunctional membrane of a muscle fibre. (3) A.c.-coupled triangular voltage pulses were injected into the bath adjacent to the patch electrode, sealed onto the surface membrane of a muscle fibre and recorded as square current pulses[8]. All three techniques produced essentially similar results and indicate that the rise and the fall time of our recording system is <100 µs. To check the efficiency (number of pulses injected per pulse recovered) of our recording system for collecting injected pulses of different durations, it was necessary either to locate the patch electrode on membrane which did not exhibit channel activity or to fill the patch electrode with glutamate-free saline. Otherwise

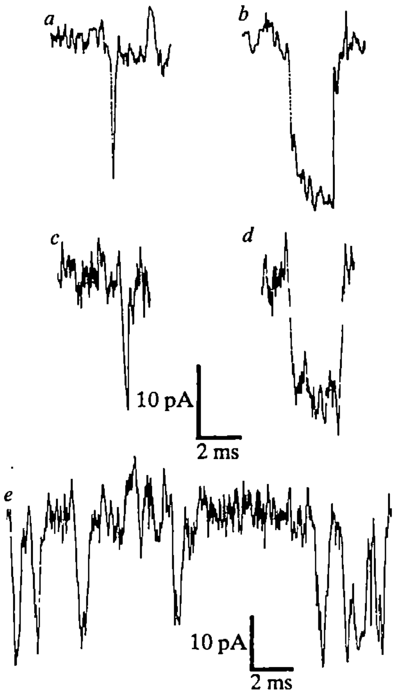

Fig. 1 Calibration pulses and single glutamate channels of locust extrajunctional muscle membrane recorded at a bandwidth of d.c. to 10 kHz. The square calibration pulses of rise time ~1 µs were injected from a saline-filled micropipette (resistance <1 M) into the bath containing a muscle preparation. The micropipette was placed to within 100 µm of a patch electrode sealed onto extrajunctional muscle membrane (see text). *a*, *b*, Typical recordings for a 65 µs and a 1.25 ms calibration pulse, respectively. *c* and *d* show single glutamate channels of comparable durations to the calibration pulses in *a* and *b*. Note that the amplitudes of the channels in *c* and *d* are approximately equal. *e*, Typical example of single channel activity with channel lifetimes ranging from ~50 µs to 1 ms. Records *c*–*e* were obtained in the presence of 5×10^{-5} M L-glutamate from a voltage-clamped muscle fibre (clamp potential −125 mV). *c* and *d* were obtained from the same site and *e* from a different site on the same muscle fibre. Temperature ~20 °C. Time and current calibrations were the same for *a*–*d*.

it was sufficient to use low (such as 10^{-5} M) concentrations of L-glutamate in the patch electrode, thereby generating only a low frequency of channel events to ensure that the time courses of at least some of the calibration pulses were not influenced by accompanying glutamate channels. There is close agreement between the duration of the square pulse injected into the bath and the recovered pulse as measured by the computer. For example, with an input pulse of mean duration 65 ± 0.01 μs (±s.d.), an output pulse of mean duration 70 ± 0.04 μs was obtained. Note that a square pulse, which has its rise and fall times limited, appears as an inverted triangle or trapezoid (Fig. 1*a*). In our system, a 100 μs pulse appears at the output as a triangle with its amplitude approximately equal to that of the injected square pulse but with the base of the triangle ~200 μs long. With close attention to the setting of the comparator level during measurement of channel lifetimes, we can reliably detect at least 90% of channel openings and closings of 50–100 μs duration. In addition, our calibration technique indicates that the measured durations for channel openings and closings are within 20% of their true value for events between 50 and 100 μs. As we obtained excellent agreement between recovered durations and input durations for calibration pulses of duration >100 μs, we are confident that our recording and analysis techniques give accurate information on channel openings and closings >100 μs.

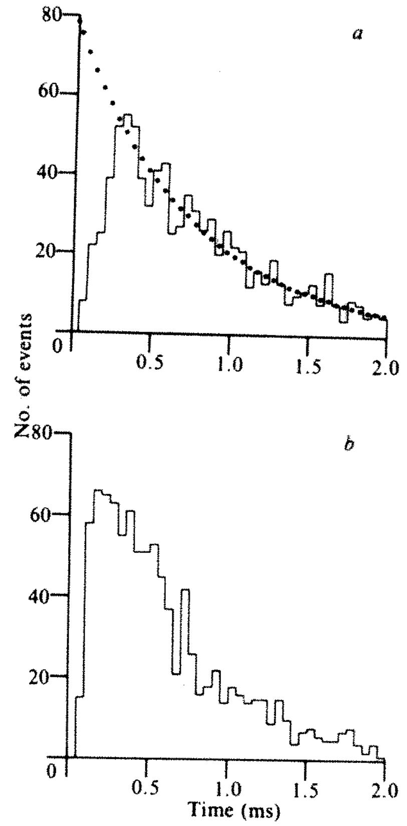

Fig. 2 Frequency distributions of glutamate channel lifetimes. *a*, Lifetime distribution for single glutamate channels recorded from an extrajunctional site with 5×10^{-5} M L-glutamate in the patch electrode. The data were obtained from a voltage-clamped muscle fibre (clamp potential −125 mV) and at a recording bandwidth of d.c. to 10 kHz. The peak in the lifetime distribution occurs at ~325 μs (bin no. 7). The dotted line, which is the best fit exponential to the falling phase of the distribution, was fitted by the least-squares method using the data in bins 6–40 (0.275–1.975 ms). The time constant of the exponential (τ_{open}) is 0.8 ms. Note the discrepancy between the observed number of short (≤250 μs) lifetimes and the number of events predicted by an exponential distribution of lifetimes. All recordings were obtained at a temperature of ~20 °C. *b*, Frequency distribution of channel lifetimes recorded in the presence of 10^{-3} M L-cysteate. Note that although the recording conditions were identical to those described for recording the glutamate channels (*a*), the peak in the cysteate channel distribution occurs at ~175 μs (bin no. 3) compared with ~325 μs (bin no. 7) for L-glutamate.

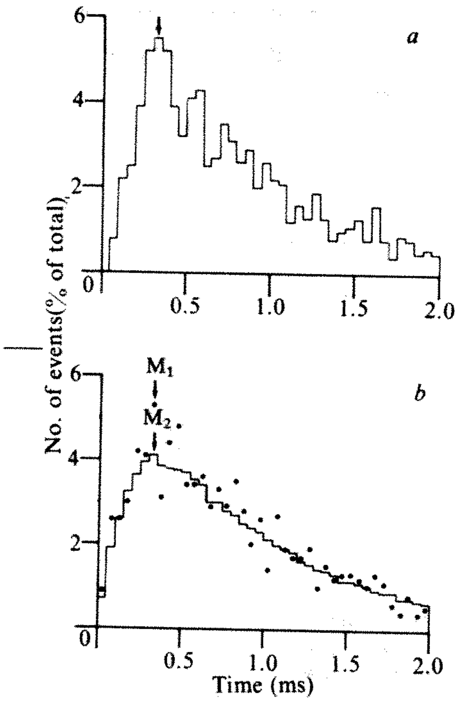

Fig. 3 Comparison of the distribution of glutamate channel lifetimes with a computer-simulated distribution. *a*, Frequency distribution of glutamate channel lifetimes recorded in the presence of 5×10^{-5} M L-glutamate (see Fig. 2*a* legend for description of recording procedure). The peak in the distribution (G) occurs at ~325 μs. *b*, Simulated frequency histograms constructed using the procedure described in the text. Two simulations are plotted, constructed from 1,000 (●) and, 100,000 (—) events. Both simulations were constructed using exponential time constants. $\tau_1 = 0.2$ ms for the first time-dependent process (state A) and $\tau_2 = 0.8$ ms for the second process (state B). The peaks (M_1 and M_2) occur at ~325 μs, coincident with the peak (see arrows) in the frequency distribution for glutamate channel lifetimes.

It is possible to monitor activity of an individual channel at a single site on a locust muscle fibre for long periods (for example 30 min) and, therefore, with an appropriate concentration of L-glutamate in the patch electrode, to collect information on a large number (for example, 1,000) of channel openings. Thus we have been able to construct histograms of channel openings using narrow (50 μs) bin widths. (Average lifetimes for quartiles of the recording period were not significantly different, indicating stationarity.) Figure 2*a* is a typical frequency histogram of lifetimes constructed from 1,000 open events recorded from a single site in the presence of 5×10^{-5} M L-glutamate. The dotted line is the best fit exponential to the falling phase of the distribution. Similar histograms have been obtained for lifetimes of channels recorded from many other preparations and with other agonists, such as L-cysteate (Fig. 2*b*). It is clear that despite the increased frequency response, our recording system histograms are still deficient in brief channel openings (of duration <250 μs), that is, the distributions are not exponential but exhibit a peak. As this deficiency could be explained only in part by the limitations of the recording system, the distributions suggest that two (or possibly more) processes may be involved in channel closure.

The open–close kinetics of desensitizing channels—bursts of channel openings separated by relatively long quiet periods[3,9,10]—make it difficult to obtain the large number of events needed to construct reliable histograms of channel lifetimes in the absence of Con A. We cannot be certain, therefore, that this lectin does not influence the lifetime of the glutamate channel, although the measured mean lifetimes of channels gated by extrajunctional receptors in Con A-treated and untreated muscle preparations are not significantly different when determined from data recorded using a 1 kHz low pass filter[5]. In addition, the measured mean channel lifetime of channels recorded with a 10 kHz amplifier, and with 5×10^{-5} M glutamate in the patch electrode, is ~1 ms—significantly shorter than the measured mean lifetimes of the glutamate channel (2–2.5 ms) reported previously using an amplifier with a more restricted bandwidth[5].

As a first approximation, the frequency distributions of lifetimes for locust glutamate receptors with 5×10^{-5} M glutamate can be described by two exponentials, the process characterized by one exponential having the effect of delaying the observed event of channel closure which is characterized by the other exponential. To test this idea we have attempted to simulate the frequency histograms of channel openings in the following way. A random number was selected from an exponential distribution with a mean corresponding to the estimated time constant of the first time-dependent process (transition from first open state [state A] to second open state [state B]). This assumes that transition from state B to state A has a low probability ($k_3 \gg k_{-3}$, see model below). A second random number was selected from another exponential distribution with a mean corresponding to the estimated time constant of the second time-dependent process (transition from open state B to closed state). The two random numbers were summed to produce a simulated channel opening. Figure 3*b* illustrates two frequency histograms, one constructed from 1,000 such events, the other from 100,000 simulated events. Initially the two time constants were estimated from the frequency histograms of real data and then refined by trial and error until the simulated histogram matched that for the real data. There is close agreement between the simulated distributions of channel lifetimes and the real data for the glutamate channel illustrated in Fig. 2*a*, suggesting that if channel closure is a two-step process, then in the case of the glutamate channel the rate of decay of state A is about four times faster than that of state B.

Cyclic kinetic schemes containing two open states have been proposed[11,12] for channels gated by acetylcholine receptors on vertebrate skeletal muscle but the three-state sequential model of Del Castillo and Katz[13] with two closed states is generally favoured for this system, that is,

$$\begin{array}{ccccc} nA+R & \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} & A_nR & \underset{k_{-2}}{\overset{k_2}{\rightleftharpoons}} & A_nR^* \\ \text{closed} & & \text{closed} & & \text{open} \end{array}$$

This scheme describes the binding of an undefined number (n) of agonist molecules to the receptor (R) to form an intermediate closed state, A_nR, which then makes the transition to the open channel state A_nR^*. Obviously the model does not adequately describe the data for locust glutamate receptors because it implies that histograms of channel lifetimes should be fitted by a single exponential function. Instead we propose that the following cyclic model, modified from the desensitization scheme developed by Katz and Thesleff[14] for the acetylcholine receptor, is a reasonable working hypothesis for the operation of glutamate-gated channels in locust muscle:

$$\begin{tikzcd}
\text{closed} & \text{closed} \\
nA+R \arrow[r, shift left, "k_1"] & A_nR \arrow[l, shift left, "k_{-1}"] \arrow[d, "k_2"] \\
nA+R^* \arrow[u, "k_4"] \arrow[r, shift left, "k_{-3}"] & A_nR^* \arrow[l, shift left, "k_3"] \\
\text{(state B) open} & \text{open (state A)}
\end{tikzcd}$$

This model includes the two open states anticipated by our lifetime data. Because the scheme includes two irreversible steps (k_2, k_4), an energy supply would be required to maintain the steady state[14,15]. Its advantage is that it provides a mechanism for dependence of channel lifetime on agonist concentration which does not require multiple binding sites for the agonist[5] because the back reaction described by k_{-3} depends on the concentration of agonist.

We thank Mr A. Tivey for technical assistance and Dr T. F. Palmer for helpful discussions. This work was supported by SERC grants to P.N.R.U. R.P.R. was a SERC Senior Visiting Fellow.

Similar mode of action of pyrethroids and DDT on sodium channel gating in myelinated nerves

Henk P. M. Vijverberg, Johan M. van der Zalm & Joep van den Bercken

Department of Veterinary Pharmacology, Pharmacy and Toxicology,
University of Utrecht, Biltstraat 172, 3572 BP Utrecht,
The Netherlands

Synthetic pyrethroids are a new class of highly active insecticides with great potential for practical application[1]. They are generally recognized as neurotoxicants that act directly on excitable membranes[2,3]. Previous studies have shown that the effect of the pyrethroid allethrin closely resembles that of the classical insecticide dichlorodiphenyl trichloroethane (DDT) in the peripheral nervous system of *Xenopus laevis*[4,5]. Both compounds induce intense repetitive activity in sense organs and in myelinated nerve fibres. In the lateral-line sense organ this repetitive activity increases with cooling, a phenomenon that may be related to the negative temperature coefficient of toxicity of DDT[6] and pyrethroids[7] in insects. In frog node of Ranvier, DDT slows the closing of sodium channels that open during depolarization[8,9] so that a prolonged sodium tail current persists after the membrane has been repolarized. We have recently found that the pyrethroid allethrin[10] causes a similar sodium tail current in the nodal membrane of *Xenopus*. Pyrethroids[11,12] and DDT[13,14] are also known to cause prolongation of the sodium current together with repetitive activity in nerve fibres of invertebrates. The prolonged sodium current is thought to be directly responsible for this repetitive activity[3,15], and it has been suggested that the sodium channel in the nerve membrane is the major target site of pyrethroids and DDT-like compounds[10,12]. We have now investigated the mechanism by which pyrethroids and DDT prolong the sodium current in *Xenopus* nodal membrane. Our results show that these compounds—despite marked differences in chemical structure—modify sodium channel gating in a strikingly similar way and reduce selectively the rate of closing of the activation gate.

The experiments were carried out on voltage-clamped[16] myelinated nerve fibres from the sciatic nerve of *X. laevis* at 15 °C. Potassium currents were eliminated by applying tetraethylammonium (TEA) and by substituting Cs^+ for K^+. Allethrin ((±)-*cis*, *trans*-(±)-allethrin), permethrin ((±)-*cis*, *trans*-permethrin) and DDT (*p,p'*-DDT) were first dissolved in ethanol and then suspended in the external solution so that the

0028-0836/82/070601—03$01.00

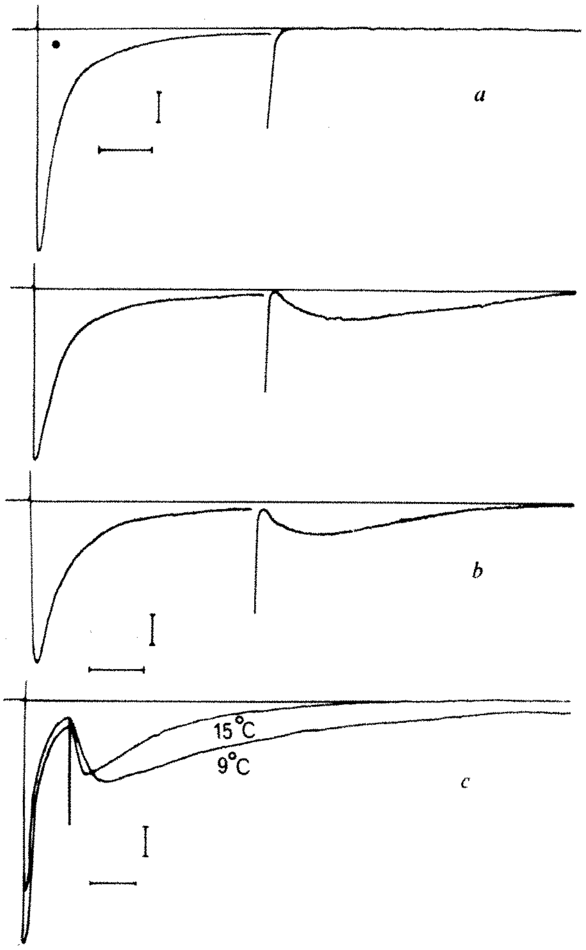

Fig. 1 Modification of sodium currents by pyrethroids and DDT. Recordings of sodium currents elicited by a depolarizing test pulse together with baseline level. Temperature 15 °C. *a*, Before (upper trace) and after (lower trace) exposure to 20 μM allethrin. *b*, After exposure to 40 μM DDT. *c*, After exposure to 10 μM permethrin. In *c* two traces are superimposed, recorded at the temperatures indicated. Test pulse amplitude: 60 mV (*a*), 70 mV (*b*, *c*). The insecticides were applied by a single perfusion of three to six times the volume of the pool bathing the node. The membrane was held at the potential at which $h_\infty = 0.70$ (−70 mV). Test pulses were preceded by a 100-ms conditioning prepulse to −120 mV to remove resting sodium inactivation. Linear parts of capacitive and leakage currents were electronically subtracted. Sodium currents were filtered at 5 kHz by an active two pole low-pass filter. Time constants of tail currents were calculated using a least squares algorithm. The external solution contained (in mM): Na^+ 104.4, Cs^+ 2.2, Ca^{2+} 1.8, TEA^+ 12, Cl^- 122.2 and HEPES 2.7; *p*H was adjusted to 7.3 with approximately 1.5 mM NaOH. The ends of the fibre were cut in 120 mM CsCl. Vertical bars, 1 nA; horizontal bar, 2 ms (*a*, *b*), 10 ms (*c*).

final nominal concentration was 10–40 μM. The amount of ethanol in the final solution was below 0.5% (v/v), which was found to be without effect in control experiments.

Allethrin and permethrin only slightly affected sodium currents during step depolarizations of the membrane. Peak sodium current amplitude was slightly reduced and the declining phase was slightly prolonged, but the rate of rise remained unaffected. The effect of allethrin and permethrin was most marked after the membrane was repolarized to holding potential. In untreated nodes the sodium current was always rapidly turned off by repolarization, whereas in the pyrethroid-treated nodes a large sodium tail current persisted (Fig. 1*a*,*c*). DDT also induced a sodium tail current after repolarization without seriously affecting sodium currents during depolarization (Fig. 1*b*), as previously reported[8,9]. The rate of decay of the tail current was independent of the amplitude and duration of the depolarizing test pulse. The decaying phase of the tail current was fitted by a single exponential with a time constant of 9.8 ± 1.2 ms (mean ± s.d., number of nodes *n* = 6) for allethrin, 17.4 ± 0.3 ms (*n* = 3) for permethrin and 3.7 ± 1.6 ms (*n* = 3) for DDT. At lower temperatures the exponential decay of the tail currents was markedly slowed, as illustrated in Fig. 1*c* for permethrin.

In pyrethroid- as well as DDT-treated nodes the membrane conductance during the tail was proportional to the degree of sodium activation during the test pulse (Fig. 2*a*). When the sodium current during the test pulse was inactivated to various degrees by varying the prepulse potential, the tail current amplitude was reduced proportionally (Fig. 2*b*). The potential dependence of sodium activation and sodium inactivation was not significantly affected by the insecticides. The magnitude of the tail current also depended on the duration of depolarization. After very short test pulses there was almost no tail current; with increasing duration of test pulse the amplitude of the tail current rapidly increased, reached a maximum and slowly declined with longer depolarizations. These results show that in pyrethroid- as well as DDT-treated nodes the number of sodium channels activated during the tail was always proportional to the number of sodium channels which had opened during depolarization, suggesting a precursor–product relationship[8] between open sodium channels and sodium channels affected by the insecticides and indicating that pyrethroids and DDT preferentially interact with open sodium channels.

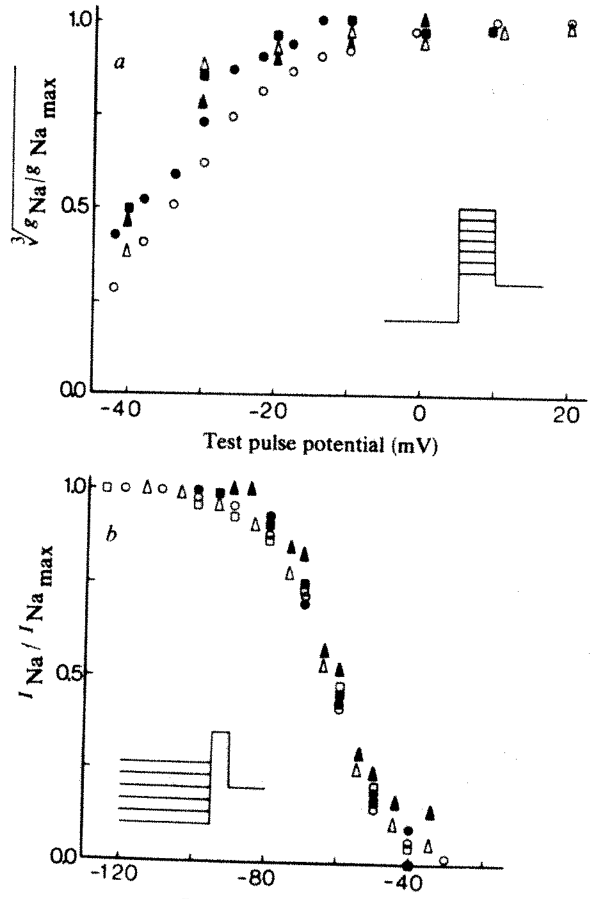

Fig. 2 *a*, Dependence of tail current amplitude on sodium activation. Sodium currents were elicited by 8-ms depolarizing test pulses of various amplitudes. Tail currents were extrapolated to the moment of repolarization and tail conductance (closed symbols) was normalized according to the procedure commonly used for sodium conductance[24] (open symbols). *b*, Dependence of tail current amplitude on sodium inactivation. Sodium currents were elicited by a standard test pulse (60 mV, 3 ms) following 100-ms conditioning prepulses of various amplitudes. Open symbols, sodium current during test pulse; closed symbols, tail current. Nodes treated with allethrin (triangles), permethrin (squares) or DDT (circles). Temperature 15 °C. Insets indicate voltage steps.

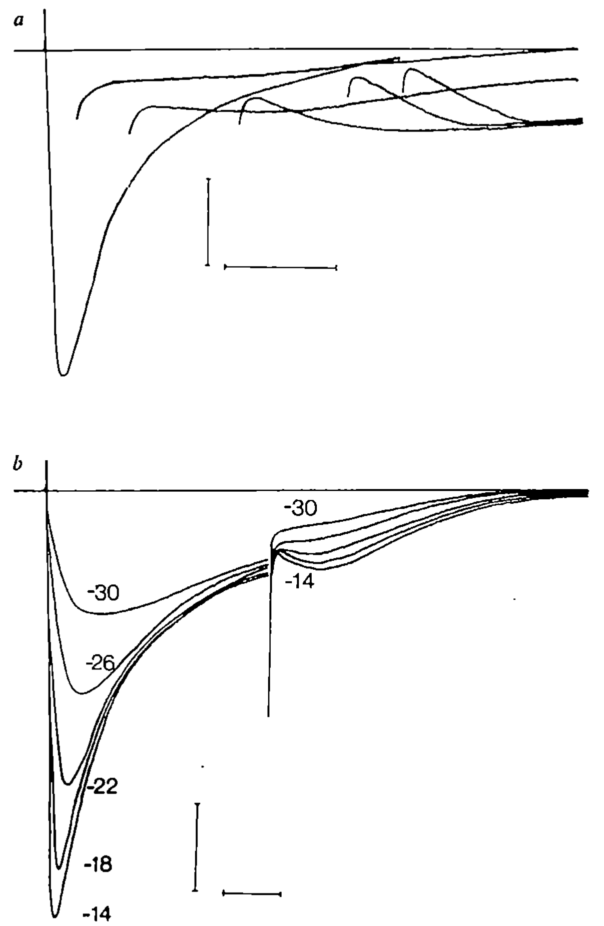

Fig. 3 Influence of duration and amplitude of depolarization on the shape of the tail current. Temperature 15 °C. *a*, Five superimposed traces of sodium currents elicited by 60-mV test pulses of 0.5, 1.5, 3.5, 5 and 6 ms, respectively, together with baseline level in a node treated with 20 μM allethrin. Following short test pulses the decay of the tail current was monotonic, whereas after longer test pulses an initial increase of the tail current gradually developed. *b*, Five superimposed traces of sodium currents elicited by 8-ms test pulses to the membrane potentials indicated together with baseline level in a node treated with 40 μM DDT. The initial increase of the tail current gradually developed with increasing amplitude of depolarization. Vertical bar, 0.5 (*a*) and 1 (*b*) nA; horizontal bars, 2 ms.

It was also found that the shape of the initial phase of tail current strongly depended on amplitude and duration of depolarization, with essentially the same results for all three insecticides. After small or short test pulses the decay of the tail current was always monotonic. With increasing amplitude and also with increasing duration of test pulse, however, the tail showed a marked initial rise before the exponential decay (Fig. 3*a*,*b*). Apparently the shape of the tail current depends on the degree of sodium inactivation at the moment of repolarization. In terms of the classical Hodgkin–Huxley model of sodium channel gating[17] this can be most readily explained by postulating that pyrethroids and DDT selectively reduce the rate of closing of the activation (m) gate in a fraction of the sodium channels that open during depolarization. After test pulses producing little inactivation, sodium channels which are not affected close as rapidly as normal, but those modified by the insecticides will close more slowly and a slowly decaying tail current will remain. Modified sodium channels are still subject to inactivation (see Fig. 3*a*) and at the end of test pulses that cause almost complete inactivation, most h-gates will be closed. On repolarization to holding potential, h-gates will start to reopen, causing modified channels to become conductant again because the closing of their m-gate is delayed. This mechanism adequately accounts for the development of a hooked tail current with increasing duration and amplitude of depolarization.

Some nodes treated with the pyrethroids or DDT failed to show an initial increase in the tail current, even after large depolarizations lasting for up to 50 ms. These nodes behaved identically to the other nodes in every respect except that they had a high degree of slow sodium inactivation[18]. Thus at the moment of repolarization many sodium channels are still open and the initial increase in the tail current will be masked by a large instantaneous sodium current.

Our hypothesis that these insecticides selectively reduce the rate of closing of the activation gate of the sodium channel is fully supported by the observation that in DDT-treated frog nodes the off-response of asymmetrical displacement currents was slowed down, while the on-response was not altered[19]. The similarity between the action of DDT and pyrethroids predicts that pyrethroids will have qualitatively similar effects on nodal displacement currents. Recently we have found that other pyrethroid insecticides, including some cyanophenoxybenzyl pyrethroids, also induce a persistent sodium tail current in *Xenopus* node of Ranvier (ref. 20 and H.P.M.V. and J.v.d.B., unpublished observations), indicating that the mechanism described here may apply to pyrethroids in general. An additional argument in favour of a similar mode of action of pyrethroids and DDT and its analogues is the existence of a high degree of non-metabolic cross-resistance in the housefly to these two classes of insecticide due to a common genetic factor (*kdr*) that presumably leads to nerve insensitivity[21,22].

The present results suggest that pyrethroids as well as DDT[8] interact with sodium channels having both the m-gate and h-gate open, and thereby stabilize the open configuration of the m-gate. On repolarization the sodium channel changes state[23] and the tail current slowly decays to zero level with a single exponential time course which is independent of tail current amplitude. This indicates that the relaxation of the m-gate of the modified sodium channels is determined by an apparent unimolecular first-order process. Differences in rate of decay of the tail current induced by the three compounds can be accounted for by differences in rate of this relaxation process. Furthermore, the marked prolongation of the tail current on cooling indicates that the relaxation process has a positive temperature coefficient which may underly the reversed temperature dependency of repetitive activity[4,5] caused by pyrethroids and DDT. Whether pyrethroids and DDT compete for the same site in the nerve membrane remains to be elucidated.

Selective killing of leukaemia cells by antibody–toxin conjugates: implications for autologous bone marrow transplantation

Keith A. Krolick, Jonathan W. Uhr & Ellen S. Vitetta

Department of Microbiology, University of Texas Southwestern Medical School, Dallas, Texas 75235, USA

The recent development of tumour-reactive monoclonal antibodies has stimulated interest in their use in targeting toxic agents to tumour cells. One such approach involves the covalent coupling of tumour-reactive antibodies to the toxic peptide of the plant toxin, ricin. Such conjugates are highly effective in killing various tumour cells *in vitro*[1–6]. Here we have used the murine B-cell tumour, BCL$_1$, in an adoptive transfer system capable of detecting 1–10 tumour cells, to demonstrate the effectiveness and specificity of an anti-immunoglobulin(Ig)–ricin A chain conjugate in deleting tumour cells from infiltrated murine bone marrow. We report that the transferred cells were able to repopulate the haematopoietic system of lethally irradiated mice and that in most mice the tumour did not recur. We discuss the implications of this approach for autologous bone marrow transplantation following supralethal tumour therapy.

The murine BCL$_1$ tumour is in many respects similar to the prolymphocytic variant of human chronic lymphocytic leukaemia (CLL)[7–9]. The malignant cells are of B-cell origin and carry immunoglobulin on their surface. BCL$_1$ grows primarily in the spleen and blood of recipient mice with invasion of the bone marrow occurring only later in the course of the disease[7]. Depending on the number of tumour cells injected, recipient mice survive for 3–5 months. We have shown previously that if tumour cells are treated *in vitro* with an antibody specific for the variable region of the surface immunoglobulin molecules (anti-idiotype antibody) covalently coupled to the A chain of ricin, protein synthesis is irreversibly inhibited and the cells are killed[1]. In such experiments, inhibition of protein synthesis correlated well with the percentage of tumour cells in the treated population. However, as injection of only 10 BCL$_1$ cells into normal BALB/c mice will induce tumour formation[10], the adoptive transfer assay represents a more sensitive measurement of the number of residual viable tumour cells in a treated cell population. The extent of tumour cell death is particularly important when comparing this technique with other procedures which eliminate tumour cells bearing specific markers.

The antibody used in the present studies was an affinity-purified polyvalent rabbit anti-mouse immunoglobulin (RαMIg) which binds to surface immunoglobulin on both BCL$_1$ tumour cells and normal B cells[11]. An affinity-purified rabbit anti-ovalbumin (RαOVA) antibody was used as a control. As described previously[1], the antibodies were covalently coupled to the A chain of ricin using the heterobifunctional cross-linker *N*-succinimidyl-3-(3-pyridyldithio)propionate (Pharmacia). The preservation of antibody activity and the presence of A chain in the conjugate were established by solid-phase radioimmunoassay. Antibody–A chain conjugates were reacted with antigen (mouse immunoglobulin or OVA) and the presence of antibody or A chain was subsequently demonstrated by binding of radiolabelled antibodies directed against rabbit immunoglobulin or ricin A chain. It was confirmed that the conjugates could kill BCL$_1$ cells *in vitro*.

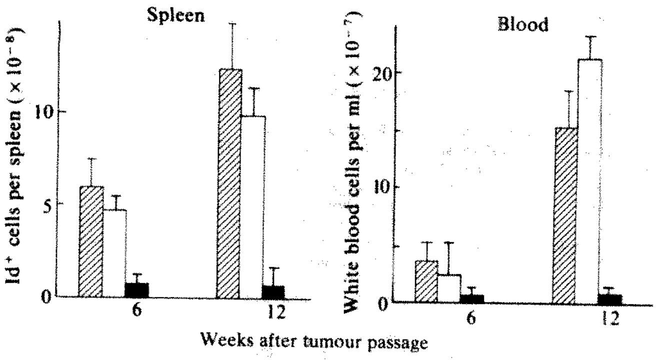

Fig. 1 Adoptive transfer of spleen cells treated with RαMIg–A chain from BCL$_1$-bearing mice. 10^7 spleen cells, containing 8×10^6 tumour cells, were treated at 4 °C for 15 min with 1 μg ml^{-1} of either RαMIg–A chain (■) or RαOVA–A chain (□). Treated cells, as well as untreated cells (▨), were washed and injected i.v. into groups of five normal BALB/c mice (10^4 cells per mouse). At 6 and 12 weeks after adoptive transfer, recipient mice were killed and examined for Id$^+$ (tumour) cells in the spleen, and for leukaemia.

Spleen cells ($1–10 \times 10^5$) from BCL$_1$-bearing mice were treated at 4 °C for 15 min with an optimal concentration of the specific (RαMIg–A) or control (RαOVA–A) antibody conjugate. Approximately 80% of the spleen cells in the populations used were tumour cells, as judged by immunofluorescent analysis after staining with anti-BCL$_1$ idiotype and by morphology. After treatment, 10^4 cells were injected into normal BALB/c mice. A group of mice also received untreated cells. At 6 and 12 weeks after adoptive transfer, recipient mice were killed and examined for presence of tumour cells in the spleen and for leukaemia. As shown in Fig. 1, untreated cells or cells treated with the control conjugate induced significant tumour formation. Animals receiving cells treated with RαMIg–A chain showed a concentration of Id$^+$ cells just above the level of control staining (5–10%) and this number did not increase between 6 and 12 weeks. Furthermore, white blood cells in RαMIg–A chain-treated mice never exceeded levels observed in normal mice ($5–10 \times 10^6$ ml^{-1}). Therefore, it is probable that treated animals contained no viable tumour cells, but we cannot exclude the possibility that there was a small number of tumour cells whose growth was inhibited by an immune response transferred with the treated splenocytes. To determine how many viable tumour cells would have been necessary to induce tumour formation at 12 weeks, additional experiments were performed using *untreated* tumour cells. In these experiments, groups of 35 mice received 1, 10 or 100 BCL$_1$ tumour cells and the time at which hepatosplenomegaly became apparent was noted. At 12 weeks after transfer of tumour cells, 95% of the animals receiving 10 tumour cells and 43% of those receiving 1 tumour cell had overt tumour (Table 1). Based on these experiments, we estimate that animals injected with spleen cells treated with RαMIg–A chain (Fig. 1) received <10 viable tumour cells. Thus, by using an inoculum of 10^4 tumour cells, we eliminated at least 99.9% of the cells.

One treatment of patients with disseminated neoplasia involves vigorous chemotherapy/radiotherapy with autologous bone marrow rescue[12]; bone marrow is removed before the patient is treated with supralethal chemotherapy and/or radiotherapy to kill all tumour cells. The autologous bone marrow is then injected into the patient to reconstitute the haematopoietic system. One major problem with this approach is that the bone marrow may contain tumour cells. We therefore applied the antibody-A chain technique to treat marrow cells from BCL$_1$-bearing mice (10–20% BCL$_1$ cells) with antibody–A chain

Table 1 Time required for small doses of tumour cells to induce hepatosplenomegaly in BALB/c recipients

No. of BCL$_1$ cells injected	Weeks after transfer	% Tumour-positive mice*
100	9	94
	12	100
10	9	69
	12	94
1	9	17
	12	43

The appearance of hepatosplenomegaly corresponds to plateau levels of Id$^+$ cells in the spleen, and mild leukaemia.

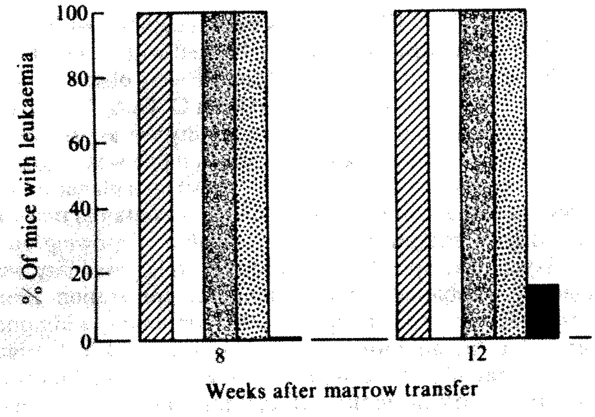

Fig. 2 Adoptive transfer of bone marrow cells treated with RαMIg–A chain from BCL$_1$-bearing mice into lethally irradiated recipients. 10^6 bone marrow cells, containing $1–2\times10^5$ tumour cells, were left untreated (▨), or were treated with RαMIg (▩), RαMIg plus C′ (▦), RαMIg–A chain (■), or RαOVA–A chain (□). Groups of 20 mice received 10^6 marrow cells per mouse. Every 2 weeks after adoptive transfer, mice were examined for leukaemia.

conjugates to eliminate tumour cells, but not stem cells, from the marrow. Preliminary experiments showed that such lethally irradiated mice could be rescued with an intravenous injection (i.v.) of 10^6, but not 10^5, normal bone marrow cells. Therefore, 10^6 marrow cells treated with specific or control conjugates or specific antibody and complement (C′) were injected into lethally irradiated (750 rad) mice.

Although all mice were rescued with 10^6 marrow cells, only those animals receiving marrow treated with RαMIg–A were leukaemia-free 8 weeks later (Fig. 2). However, 12 weeks after marrow transfer, 3/20 of the mice receiving RαMIg–A-treated marrow were leukaemic. Based on the number of animals which became leukaemic and the length of time necessary to achieve a leukaemic state (see Table 1), it was estimated that 1–10 tumour cells remained in the RαMIg–A chain-treated marrow. Thus, as the original 10^6 marrow cells injected contained 10^5 tumour cells, we estimate that the specific conjugate eliminated 99.9% of the tumour cells while preserving sufficient numbers of stem cells to repopulate the mice. Moreover, other experiments (not shown) have demonstrated that the repopulated tumour-free mice contain normal numbers of T and B cells in their spleens.

Note that the treatment of marrow with RαMIg plus C′ required 250 times more antibody for optimal cytotoxicity (20%) than treatment with RαMIg–A chain. Although the RαMIg plus C′ eliminated an estimated 90–95% of the tumour cells from the treated marrow, the recipient mice rapidly developed leukaemia, emphasizing the advantage of using antibody–A chain compared with C′-mediated cytotoxicity.

These results indicate that: (1) almost all (>99.9%) BCL$_1$ tumour cells bear surface immunoglobulin, that is, the BCL$_1$ tumour does not have a major pre-B cell component; (2) treatment with RαMIg–A chain conjugate eliminates Ig$^+$ tumour cells from the marrow of most mice but leaves sufficient numbers of stem cells intact; (3) neoplastic B cells can be eliminated by a conjugate using an antibody that is not tumour-specific. Thus, the above approach to autologous bone marrow transplantation, requires only a tumour-reactive, stem cell-non-reactive antibody.

Further experiments are needed to determine whether all BCL$_1$ tumour cells can be killed by the above approach. We emphasize that spontaneous B-cell leukaemias in man could have malignant pre-B cells[13], that is, surface Ig$^-$ in addition to surface Ig$^+$ leukaemic cells. Elimination of Ig$^-$ leukaemic cells would require treatment with a monoclonal antibody to a differentiation antigen that is expressed on pre-B cells and not stem cells.

Mitochondrial transformation of mammalian cells

Mike A. Clark & Jerry W. Shay*

Department of Cell Biology, The University of Texas Health Science
Center at Dallas, 5323 Harry Hines Boulevard, Dallas,
Texas 75235, USA

Resistance to the antibiotics chloramphenicol (CAP$^{\rm r}$) and efrapeptin (EF$^{\rm r}$) in mammalian cells is cytoplasmically inherited[1,2]. We demonstrate here that purified mitochondria obtained from CAP$^{\rm r}$ and EF$^{\rm r}$ cells are taken up by endocytosis and transfer antibiotic resistance to chloramphenicol-(CAP$^{\rm s}$) and efrapeptin-(EF$^{\rm s}$) sensitive cells. The resultant cells, termed mitochondrial transformants, are stably resistant to the antibiotics and are produced with high efficiency. The ability to transfer antibiotic resistance using mitochondria supports the notion that CAP$^{\rm r}$ is due to a mutation of the mitochondrial DNA[3]. This technique of mitochondrial-mediated transfer of antibiotic resistance may provide a novel means for studying mitochondrial genetics in mammalian cells.

The antibiotics chloramphenicol and efrapeptin inhibit mitochondrial protein synthesis and ATPase, respectively, thereby killing sensitive (wild-type) mammalian cells. Various mutant cell lines have been isolated[2,4] which are resistant to these drugs; we used these mutants to investigate the ability of isolated mitochondria[5] to transfer resistance to the antibiotics. In these experiments we produced antibiotic-resistant cells by mixing purified resistant mitochondria with sensitive (wild-type) intact cells and selecting the transformants by using antibiotics. The following are evidence that we were able to transfer antibiotic resistance via isolated mitochondria: (1) mitochondria obtained from antibiotic-resistant cells previously incubated with the vital non-toxic laser dye rhodamine 123, which specifically stains mitochondria[6], accumulated in wild-type cells by endocytosis; (2) transfer of antibiotic resistance was stable even in the absence of antibiotic selection; (3) contaminating resistant parental cells were not responsible for these observations, as wild-type recipent cells had specific nuclear markers allowing positive identification of cell types; (4) the transfer was cytoplasmically determined because mitochondrial transformants were used as donors to transfer antibiotic resistance by enucleation and cybridization; (5) this transfer was UV light sensitive and appeared to be species specific; (6) there was a high cotransfer frequency of both CAP$^{\rm r}$ and EF$^{\rm r}$.

Y-1 and PCC$_4$ wild-type (CAP$^{\rm s}$ and EF$^{\rm s}$) cells (respectively obtained from the American Type Culture Collection, Maryland, and W. E. Wright, UTHSCD, Texas), plated out in medium containing 50 μg ml^{-1} CAP or 0.1 μg ml^{-1} EF, were

able to attach to the substrate. After 4–5 days the cells became vacuolated, developed pycnotic nuclei and eventually detached from the substrate (Fig. 1*b*, *c*). The incidence of spontaneous resistance to CAP or EF in these cell lines was below our level of detection ($<10^{-8}$). When CAP^s EF^s Y-1 cells were incubated with CAP^r EF^s AMT mitochondria and then challenged in CAP or EF for 2 weeks, it was observed that many CAP^r colonies, but no EF^r colonies, were produced (Fig. 1*d*, *e*). (The AMT cells were obtained from Dr N. Wivel, NIH, Maryland, and the antibiotic stability was as previously described[4].) The plating efficiency of this cell line was ~28% in the condition described.

Y-1 cells + TL-1 mitochondria in Ef

Y-1 cells + P815 mitochondria in Ef

Fig. 1 Mitochondria were obtained by homogenizing AMT (CAP^r EF^s) or TL-1 (CAP^r, EF^r) cells and removing nuclei and whole cells by low speed centrifugation (500*g*, 5 min). Mitochondria were then pelleted (20,000*g*, 20 min) and further purified on a discontinuous sucrose gradient (75,000*g*, 30 min), The mitochondria were removed from the 1.0–1.5 M sucrose interface[5]; this fraction was found to be free of nuclei and whole cells after ultrastructural examination. The DNA content of this fraction, determined by reading the absorption at 260 nm (ε, 1 mg = 27 o.d.), was found to average 1–2 μg of DNA recovered from 10^9 cells. In addition, there was no growth when purified mitchondria isolated from 2×10^6 cells were placed in culture for 2 weeks (dish *a*), suggesting that this mitochondrial fraction did not contain viable cells. Y-1 cells (EF^s, CAP^s) do not grow when challenged with 0.1 μg ml^{-1} EF or 50 μg ml^{-1} CAP (*b*, *c*, respectively). Cells to be transformed were placed in a 98-well dish (3×10^4 cells per well) with purified mitochondria. 12 h later the cells were washed and re-plated at 10^3 cells per 100 mm dish in medium containing 50 μg ml^{-1} CAP or 0.1 μg ml^{-1} EF. After 2 weeks of growth the dishes shown in the figure were fixed in methanol/acetic acid (3:1) and Giemsa-stained. Because *p*H, cell density and glucose concentration are important factors in the expression of the CAP^r phenotype, they were kept the same for all experiments. All cells were grown in Dulbecco's modified medium with 1 mg ml^{-1} glucose (with pyruvate) and 10% fetal bovine serum in an atmosphere containing 5% CO_2, *p*H 7.2. In each of the dishes shown except *a*, mitochondria (obtained from 2×10^6 cells) were incubated with 3×10^4 wild-type Y-1 cells. Y-1 cells incubated with CAP^r EF^s AMT mitochondria produced many CAP^r clones of Y-1 cells (*d*). The surviving cells were shown to be Y-1 and not AMT cells by their ability to round up and secrete steroids in response to ACTH[7]. Although the AMT mitochondria were able to confer CAP resistance, they were unable to confer EF resistance (*e*). In control experiments, CAP^s EF^s mitochondria obtained from P815 mastocytoma cells were incubated with Y-1 cells; these mitochondria were unable to confer either CAP or EF resistance (*f*, *i*, respectively). If CAP^r EF^r TL-1 mitochondria were used, both CAP-resistant (*g*) and EF-resistant (*h*) Y-1 clones grew. Similar results were obtained using PCC_4 Aza-1 wild-type recipient cells (Table 1). In these experients the PCC_4 cells have a specific nuclear marker (resistance to 8-azaguanine) allowing positive identification of cell types.

However, if the CAP^s EF^s Y-1 cells were incubated with CAP^r EF^r TL-1 mitochondria and then challenged with CAP or EF, many colonies resistant to both CAP and EF were observed (Fig. 1*g*, *h*). (The TL-1 cells were obtained from G. Getz, University of Chicago, Illinois, and the antibiotic stability was as previously described[2].) The plating efficiency of this cell line was ~30% in the cloning conditions described. One possible explanation for these results is that antibiotic-resistant cells contaminated the mitochondrial preparation and were capable of growing on a 'feeder' layer of recipient cells. However, this possibility was excluded by incubating the mitochondrial preparation alone (Fig. 1*a*) and by using recipient cells containing additional markers. That the antibiotic-resistant cells were of Y-1 origin was demonstrated by treating the cells with 100 milliunits of adrenocorticotropic hormone (ACTH) for 30 min[7]. A mean of 49 out of 50 CAP^r colonies and 47 out of 50 EF^r colonies in three separate experiments were responsive to ACTH by morphological analysis (rounding up) and fluorimetric analysis (increased steroid secretion). This result indicated that the surviving antibiotic-resistant cells were not intact AMT or TL-1 cells, which might have contaminated the mitochondrial preparation, since the AMT and TL-1 cells were fibroblasts and thus not responsive to ACTH. Similar results were obtained with the PCC_4 cell line. In these experiments, CAP^r and EF^r transformed cells were demonstrated to be PCC_4 cells by their resistance to 8-azaguanine; a nuclear mutation (HGPRT$^-$) allows the PCC_4 cells, but not AMT or TL-1 cells, to proliferate in the presence of 8-azaguanine. Mitochondria isolated from antibiotic-sensitive (wild-type) P815 cells were unable to confer CAP^r or EF^r on either Y-1 or PCC_4 cells (Fig. 1*f*, *i*). (P815 cells were obtained from W. T. Garrard, University of Texas Health Science Center, Texas.)

The production of mitochondrial transformants was dependent on the number of mitochondria added to the Y-1 or PCC_4 cells (see Table 1). It was observed that the AMT mitochondria conferred resistance to CAP but not to EF on both cell lines used, while the TL-1 mitochondria conferred CAP and EF resistance with similar frequencies. In control experiments, mitochondria obtained from CAP^s EF^s P815 cells conferred neither CAp nor EF resistance. In these experiments we observed no spontaneous mutants that were able to grow in CAP or EF in either the Y-1 or PCC_4 cells when plated at 3×10^4 cells per 10-cm dish. In addition, even if plated at higher density ($>10^6$ cells per 10-cm dish), we were unable to isolate any spontaneous stable antibiotic-resistant revertants.

If mitochondria were responsible for the transfer of antibiotic resistance, then extracts depleted of mitochondria or UV-inactivated mitochondrial preparations should be less efficient in transformation. Supernatants from the differential centrifugation which contained very few mitochondria (as determined by electron microscopy) were ~80-fold reduced in their ability to transform cells. Exposure of mitochondria to UV light also resulted in a reduction in their ability to transform antibiotic-

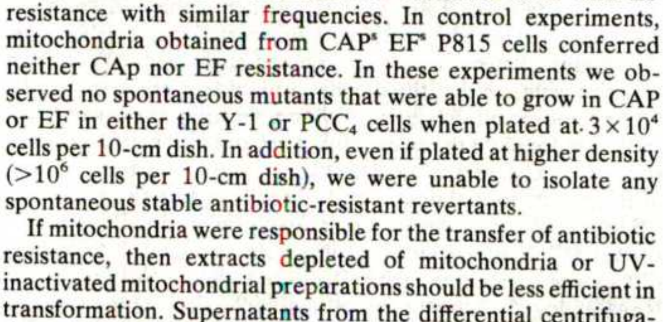

Fig. 2 AMT cells were grown in 1 μg ml^{-1} of R123 (Kodak, New York) for 30 min before homogenization. The resulting R123-stained mitochondria were then incubated with unstained Y-1 cells for 2 h before observation by fluorescence microscopy. *a*, Fluorescence and *b*, phase-contrast micrograph of the same field of cells. About 40% of all Y-1 cells contained varying numbers of fluorescent mitochondria. However, there were many cells which did not appear to incorporate any R123 mitochondria (arrow). Scale bar, 10 μm.

Table 1 No. of CAP^r or EF^r clones observed after 2 weeks of growth in antibiotics for varying numbers of mitochondria used in transformation

Source of mitochondria	No. of antibiotic-resistant colonies (>50 cells) observed 2 weeks after transformation AMT (CAP^{r}EF^s)				TL-1 (CAP^r EF^r)				P815 (CAP^s EF^s)

Mitochondria were isolated from the CAP^r EF^s AMT, CAP^r EF^r TL-1 and CAP^s EF^s P815 cell lines and incubated with the CAP^s EF^s Y-1 and PCC$_4$ cell lines as described in the text. Values are the average number (three experiments) of CAP^r or EF^r clones observed after 2 weeks of growth in either CAP or EF when varying numbers of mitochondria (1 mitochondrial equivalent = the number of mitochondria recovered from 1 cell) were incubated with a constant number (3×10^4) of Y-1 or PCC$_4$ cells. (10^6 mitochondrial equivalents contain 2.5 ng of DNA.)

sensitive cells (Table 2 shows the results as average of three experiments). A constant number of mitochondria obtained from 10^9 AMT cells were diluted into aliquots, each aliquot containing a number of mitochondria equivalent to that obtained from 10^6 cells. These aliquots were then incubated with 3×10^4 Y-1 cells. Control mitochondria that had not been exposed to UV light were able to confer CAP^r at a frequency of $\sim1.5\times10^{-3}$. However, aliquots of mitochondria that had been exposed to UV light (Sylvania germicidal UV light (G15T8) at a distance of 10 cm) showed a much reduced transformation frequency.

We then tested the stability of antibiotic resistance in the mitochondrial transformants. Twelve clones were chosen at random (six from CAP^r and six from EF^r colonies) that had been grown for 3 weeks in the presence of the antibiotic. These clones were transferred to antibiotic-free medium for 2 weeks (12–14 cell doublings) before being retested with CAP or EF; all 12 clones retained equal resistance to both antibiotics. The per cent of cells retaining their antibiotic resistance and the plating efficiencies of the transformed cells were the same as those of the parental drug-resistant strains. Furthermore, we maintained these clones for over 12 weeks in the presence of the antibiotics and all clones were stable in their transformation. There was no decrease in plating efficiency between the initial testing and after 12–14 population doublings in the absence of antibiotics.

In addition to the antibiotic resistance originally selected, other information was transferred in the mitochondrial genome to the recipient cells. After incubation of CAP^s EF^s Y-1 cells with CAP^r EF^r TL-1 mitochondria, one half of the cells were plated in dishes containing CAP and the other half in EF. Five random clones of CAP^r Y-1 cells and six clones of EF^r cells were isolated and tested for their ability to grow in the reciprocal antibiotic. All 11 clones were resitant to both antibiotics. This is in agreement with the observations of Wigler *et al.*[8], who demonstrated a high incidence of co-transfer of genetic material using purified nuclear DNA. The high antibiotic co-transfer frequency may result from incorporation of intact mitochondria into the recipient cells. This hypothesis was tested by isolating mitochondria from cells which had been treated previously with rhodamine 123 (R123), a vital dye which specifically stains mitochondria[6]. When R123-stained mitochondria were incubated with unstained Y-1 cells, uptake of the stained mitochondria was observed by fluorescence microscopy (Fig. 2).

If mitochondria were responsible for the stable transfer of antibiotic resistance, then mitochondrial transformants could be used as antibiotic-resistant donors in cybridization experiments. CAP^r and EF^r mitochondrial transformants were enucleated using cytochalasin B[9] and their cytoplasts fused to CAP^s and EF^s Y-1 cells. The rationale for producing cybrids, rather than a second generation of mitochondrial transformants, was that fewer (5×10^5) cells were needed in each experiment. These experiments demonstrated that two out of eight clones of transformants were able, in turn, to transfer antibiotic resistance, which indicated that the TL-1 and AMT transforming material was incorporated into the cytoplasm.

Not all cell lines were equally capable of acting as recipients for transformation by purified mitochondria. Murine CAP^r and EF^r mitochondria were unable to confer either CAP or EF resistance on human Lesch Nyhan cells. This result was consistent with previously published cybrid data[10] which demonstrated that CAP resistance could not be transferred between species. In addition, not all murine cell lines were equally capable of transformation. After repeated attempts, we have been unsuccessful in conferring either CAP or EF resistance to the murine C17-S1-D-T984 cell line, originally derived from a teratoma. It is not understood why there is such variability in the efficiency of mitochondrial transformation, but the above observation is consistent with previous findings which indicated that murine cell lines differ widely in their ability to incorporate isolated nuclear DNA[8]. In addition, the C17-S1-D-T984 cell line was markedly reduced in R123–labelled mitochondria uptake when compared with the Y-1 and PCC$_4$ cells, suggesting that differences in endocytosis may be important in mitochondrial-mediated transfer of antibiotic resistance.

Thus, we have used isolated mitochondria to confer CAP and EF resistance with high efficiency. There was a high co-transfer frequency and transformed cells were stable even in the absence of antibiotic selection pressure. After enucleation of mitochondrial transformants, antibiotic resistance was subsequently transferred cytoplasmically. These results suggest that either the antibiotic resistance was transferred by recombination with the recipient cell mitchondrial genome or that the recipient cell incorporated intact antibiotic-resistant mitochondria (or both). Experiments are now in progress to determine whether isolated mitochondrial DNA can also transfer antibiotic resistance.

Mitochondrial myopathies are becoming increasingly recognized as uncommon causes of muscular disorders[1] characterized by weakness and severe exercise intolerance. Electron micrographs of the muscle show gross abnormality of the mitochondrial structure. Such defects are expected to affect the energy metabolism of muscle but investigations in human subjects have necessarily been limited by the need for biopsy material. Following extensive phosphorus nuclear magnetic resonance (^{31}P NMR) measurements on isolated organs, tissues and selected parts of live animals (see ref. 2 for review), it has become possible to observe non-invasively the energy metabolism of human muscle *in vivo*[3–5]. Here, we report abnormal recovery of phosphocreatine (PCr) and *p*H after exercise of the forearm in two sisters, one of whom has been shown to have a mitochondrial NADH-coenzyme Q reductase deficiency and the other presumed to have the same defect on the basis of clinical symptoms, histology and biochemical studies of blood constituents[6]. Our results, together with studies on normal subjects and patients with impaired glycogen metabolism, allow the assessment of the relative importance of oxidative and glycolytic regeneration of high-energy phosphates during exercise and recovery.

The results of the clinical, biochemical and histological examination of the two patients have been reported previously[6]. Case 1 (L.O.), 28 yr old, was normal at birth but since early childhood has been unable to run more than a few paces. Muscular weakness has often been accompanied by nausea and sickness; the worst attack, which led to her admission and diagnosis, was precipitated by a small intake of alcohol. On that admission she had severe lactic acidosis (17.8 mM). Biopsy evidence showed structurally abnormal mitochondria with paracrystalline inclusions, and the biochemical studies established inability to oxidize NAD-linked substrates, while succinate was oxidized normally.

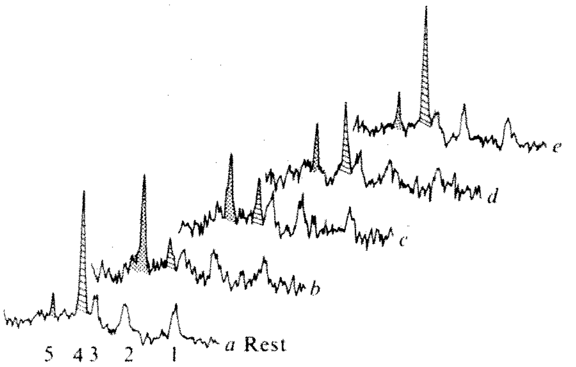

Fig. 1 ^{31}P NMR spectra of one of the patients (R.O.), taken at rest, during exercise and recovery. The signals are assigned as follows: 1, 2 and 3, the β, α and γ phosphates of ATP; 4, phosphocreatine; 5, inorganic phosphate. The inorganic phosphate and phosphocreatine signals are shaded for clarity. All spectra were accumulated at 32.5 MHz using a train of radiofrequency pulses applied at intervals of 2 s; the number of pulses was 128 for spectrum *a*, 32 for spectra *b–d*, and 64 for spectrum *e*. Spectrum *a* was recorded at rest immediately before exercise. Spectrum *b* was recorded during the last minute of aerobic exercise, and spectra *c–e* were recorded during the recovery period at 5, 9.5 and 37 min, respectively, after the end of exercise.

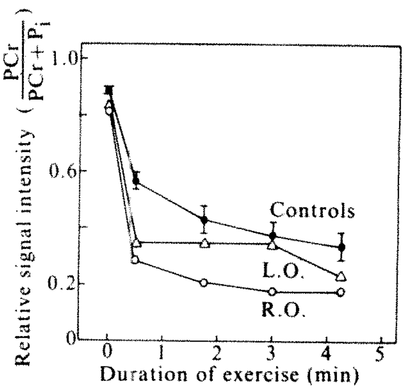

Fig. 2 Change in PCr concentration (expressed as a ratio to PCr + P$_i$) during aerobic exercise. Exercise was carried out by opening and closing the fist (L.O. and R.O.) or squeezing a rubber bulb to a pressure of 100 mmHg (controls) every 2 s for 5 min. Controls (five males and five females) were aged 22–37 yr. Values are given as ± s.e.m.

Case 2 (R.O.), 2 yr younger, with a similar medical history and more severe exercise intolerance, has a resting lactic acid concentration in blood of 4.7–7.9 mM (normal 1 mM). Biopsy showed the same histological abnormality of mitochondria as for L.O., but no biochemical studies of biopsies were undertaken in this patient. She was assumed to have the same metabolic defect as patient 1.

For the ^{31}P NMR examination, a circular radiofrequency surface coil of diameter 2.5 cm was positioned adjacent to the flexor digitorum superficialis of the right forearm. Five to ten minutes after the arm had been placed in the bore of the superconducting magnet, three spectra were collected. This procedure took about 10 min, during which time the arm remained at rest. The spectra from both patients contained the normally observed metabolites inorganic phosphate (P$_i$), PCr and ATP (Fig. 1). However, they differed quantitatively from the spectra of control subjects obtained at rest in that during the 10 min, the ratio PCr : P$_i$ gradually increased from abnormally low values (R.O., 2.3; L.O., 3.5) to nearer normal values (R.O., 4.9; L.O., 5.8; normals, 9.3 ± 2.0 (s.d.), $n = 21$). In R.O. and L.O., the intracellular *p*H at rest, measured from the frequency of P$_i$ resonance, was 7.04 ± 0.01 and 6.96 ± 0.02 (three measurements, ± s.d.), respectively, compared with a value of 7.04 ± 0.03 observed for 20 control subjects.

Light exercise was begun (opening and closing the fist every 2 s for 5 min). Spectra were collected every 75 s throughout exercise and during 30–40 min of recovery following exercise. The patients' metabolic response to exercise and their subsequent recovery were markedly abnormal. During the first minute of the very light exercise regime, the concentration of PCr decreased and that of P$_i$ increased more rapidly than in normal controls doing considerably more work (Fig. 2). By the second minute of exercise, 65–75% of the PCr had been consumed and the *p*H had fallen to 6.56 (L.O.) and 6.73 (R.O.). This change in *p*H relative to PCr consumption is normal but was achieved at much lower work loads than in control subjects. No change in the ATP concentration was detected during exercise, but with the available signal-to-noise ratio, changes of less than 20% would not be detected.

The most marked abnormality which was observed in both patients was the extremely slow return, following exercise, of the PCr and P$_i$ to their initial concentrations. Normal subjects recovered >90% of the resting PCr/(PCr + P$_i$) in less than 3 min, while in the two patients this level of recovery was not reached until 30 min or more (Fig. 3). Because the recovery process is so lengthy, the muscle may not have been at 'rest'

0028–0836/82/070608—02$01.00

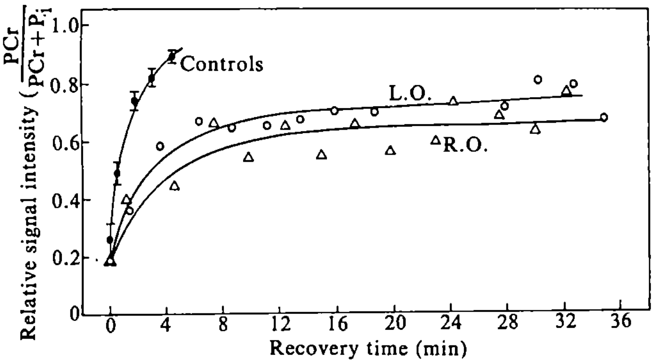

Fig. 3 Recovery of PCr/(PCr+P_i) following exercise. Exercise was carried out by opening and closing the fist every 2 s for 5 min (R.O. and L.O.), or squeezing a rubber bulb to a pressure of 100–300 mm Hg every 2 s for 7.5–21 min. Resting values of PCr/(PCr+P_i) were 0.83 (L.O.), 0.84 (R.O.) and 0.90±0.01 (controls, ±s.e.m.). Control values were obtained from four female and four male subjects aged 22–37 yr. Values are ±s.e.m.

when the first spectra were obtained, and this may account for the low PCr:P_i ratio observed before the start of exercise. Interestingly, the intracellular *p*H returned to the original level 2.5–3.5 min after the cessation of exercise (Fig. 4). The initial rate of *p*H increase was ~0.25 *p*H units min^{-1}. In eight normal individuals whose muscle *p*H in exercise decreased to an average value of 6.4, the recovery time was >9 min and the *p*H change was linear for 9 min, with a rate of 0.07 *p*H units min^{-1}.

In patients with glycogen phosphorylase deficiency the recovery of PCr results predominantly from oxidative phosphorylation. In the three such patients that we have investigated, the rate of recovery is the same as in control subjects[5]. Thus, we conclude that the recovery phase is largely governed by the rate of mitochondrial ATP synthesis ($t_{1/2}\sim 1$ min). The slow rate of PCr recovery in our two patients is consistent with a decreased rate of oxidative metabolism. In patient 1 the rate of oxidation of NAD-linked substrates in isolated mitochondria is six to seven times slower than in control subjects[6]. Interestingly, the rate of oxidative PCr recovery *in vivo* is also about six times slower in the two patients than in controls. The importance of oxidative processes in recovery is confirmed by studies in which four control subjects have undergone 1 min of exercise during ischaemia followed by 6 min of rest during which ischaemia was maintained. At the end of exercise, the PCr decreased to 50% or less of the initial value, but there was no detectable recovery of PCr during the subsequent 6 min of ischaemia. In addition, the *p*H varied by less than 0.15 *p*H units in the ischaemic rest period. On resumption of blood flow, the metabolic recovery was very rapid, the PCr returning to >90% of its control value within 2–5 min. This suggests that glycogenolysis is switched off at the end of exercise, possibly because Ca^{2+} ions are taken up by the sarcoplasmic reticulum.

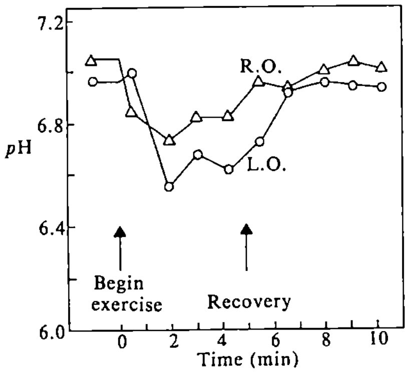

Fig. 4 Intracellular *p*H during exercise and recovery in the patients. *p*H was obtained from the chemical shift of P_i with reference to PCr as described previously[5].

In view of the high blood lactate levels that have been observed in one of the patients, the changes in intracellular *p*H on exercise are perhaps milder than might have been expected. A similar observation has been made in another patient with a mitochondrial myopathy[7]. It is possible that such people have an adaptive mechanism for removing intracellular lactate into the bloodstream. This would be consistent with the rapid recovery of intracellular *p*H following exercise.

^{31}P NMR examination of patients with muscle disease offers an objective means of assessing therapy. The patients described here have in the past received sporadic and largely ineffective treatment with menadione. It is now intended to repeat this trial of therapy with objective measurement of the response from NMR determination of the rate of rephosphorylation of creatine to PCr.

Simulated cross-bridge patterns corresponding to ciliary beating in *Paramecium*

Kazuyuki Sugino & Yutaka Naitoh

Institute of Biological Sciences, University of Tsukuba,
Ibaraki 305, Japan

It is generally accepted that bending of a cilium is caused by active sliding between outer doublets in the cilium produced by ATP-driven activation of their dynein–tubulin cross-bridges[1–3]. Changes with time in the location and extent of the active sliding regions in the outer doublets are thought to be primarily responsible for the changing shape of a beating cilium. However, using conventional techniques of biochemistry and electron microscopy, it is difficult to identify the regions on the outer doublets where active sliding occurs[4]. Here we have used computer simulation of the beating of a cilium to investigate changes in the distribution of activated cross-bridges, and hence of active sliding, in the nine outer doublets. Hereafter, the pattern of this distribution will be termed 'cross-bridge pattern'. Published data have indicated that there is a periodically changing series of cross-bridge patterns in the nine outer doublets. On this assumption, the computer mimicked relatively well the beating of a cilium of *Paramecium* in media of both normal and high viscosity. The computer also simulated flagellar-type beating[5], in which the cross-bridge patterns were modified slightly.

We used a ACOS-800 II (Nippon Electric, Tokyo) computer for simulation[6], and made the following basic assumptions: (1) active sliding occurs between adjacent outer doublets[1]. (2) The *n*th outer doublet drives its adjacent $(n+1)$th outer doublet up towards the tip when activated[7]. (3) In given chemical conditions within the cilium, the sliding velocity between adjacent doublets is constant, independent of the location and extent of the active region in a doublet pair[8,9]. (4) In given chemical conditions the stiffness of the cilium is almost constant[10] and sufficient to maintain overall spatial arrangement of the doublets during beating. (5) Sliding between the doublets is restrained only at the basal region. Therefore, bending of the doublets occurs in the region between the base and the actively sliding region[11]. (6) A

0028–0836/82/070609—03$01.00

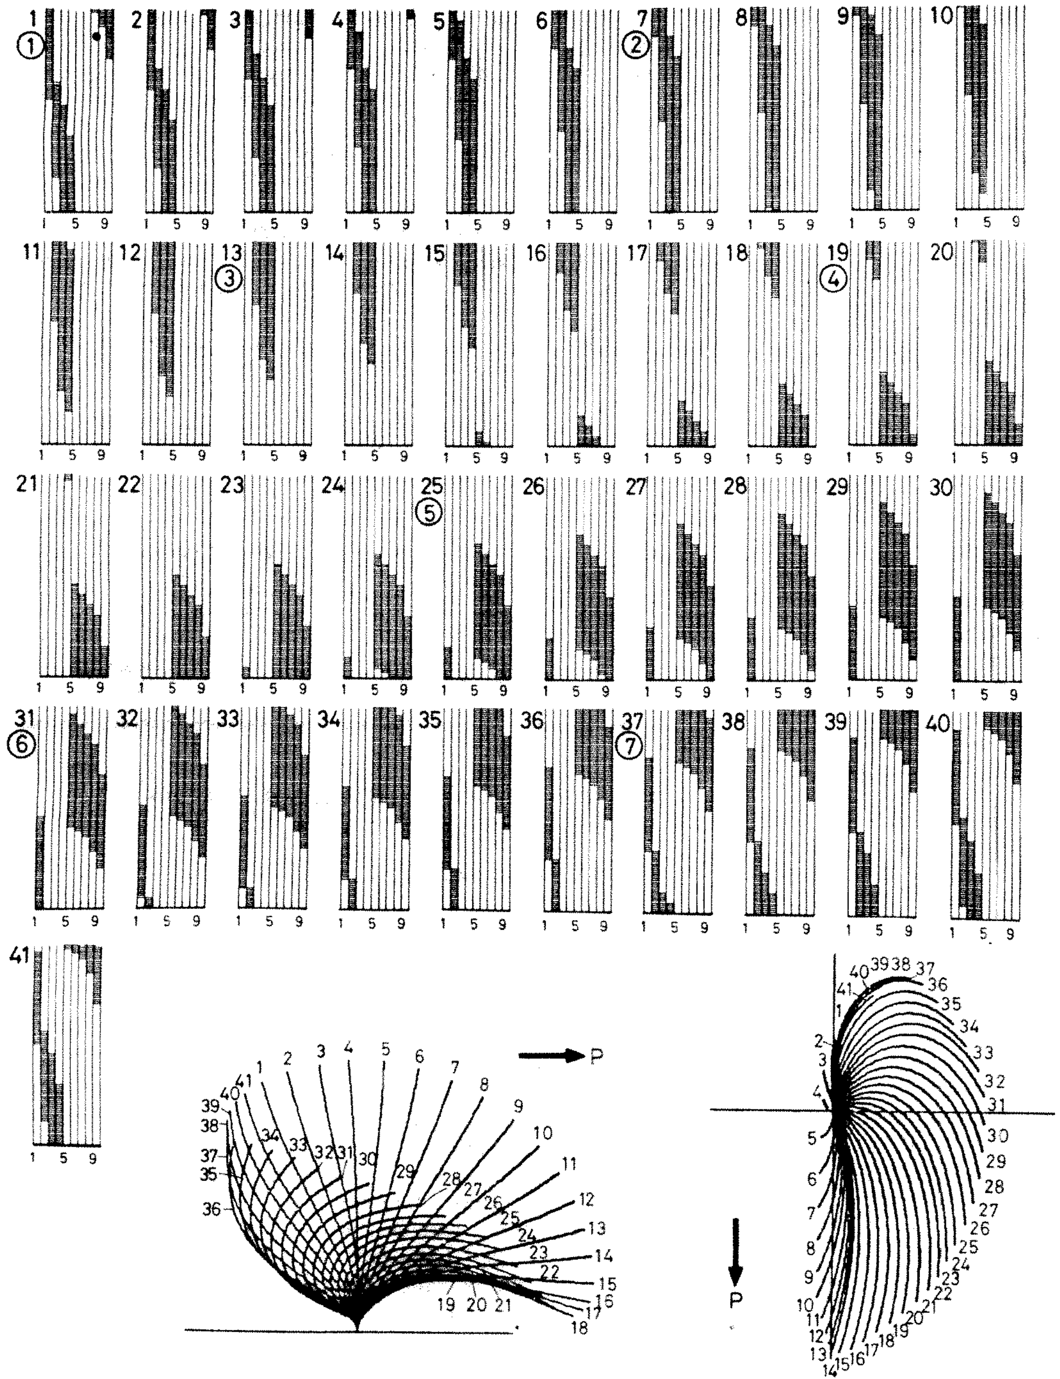

Fig. 1 Upper part, computer-estimated changes with time in the distribution pattern of the actively sliding regions in the nine outer doublets of a cilium (cross-bridge pattern) in *Paramecium* during a single beat cycle. The nine doublets are shown schematically in a plane as ten vertical lines numbered at their bases (1, 5 and 9) according to Bradfield–Afzelius[18,19]. Lines 1 and 10 correspond to doublet no. 1 (note that doublets are arranged sequentially about the circumference of the cilium). Shaded areas between the vertical lines represent the actively sliding regions. (Each small horizontal line does not necessarily indicate activated dynein–tubulin cross-bridges.) Time interval between each successive pattern was kept constant at 1/41 of the period of a single beat cycle. Lower part, computer-simulated change in the shape of a cilium of *Paramecium* during a single beat cycle. Each shape is simulated according to each cross-bridge pattern with the corresponding number in the upper part of the figure. Left, side view; right, top view. Arrows labelled P indecate posterior end of *Paramecium*.

region of active sliding between two doublets is not necessarily straight, and may be bent by forces generated by sliding between another pair of doublets. (7) Bending moment of a cilium appears as a vector sum of bending moments generated by sliding in each pair of doublets. (8) Elastic backforce exerted by a cilium when it is bent is negligible. (9) External viscosity restricts ciliary movement according to Stokes' law, that is, each element on a cilium has a viscous resistance proportional to the length and velocity of the element. (10) Bending moment of a cilium is always balanced by a moment produced by viscous resistance during ciliary beating, which causes a drag on the beating. (11) No twisting of a cilium occurs around its longitudinal axis during bending.

We introduced to the model by trial and error a successively changing cross-bridge pattern together with some degree of viscosity restriction of the cilium, until it mimicked beating of a cilium of *Paramecium*. Thus we finally estimated a periodic change in the cross-bridge pattern corresponding to ciliary beating. Figure 1 shows 41 successive changes in the cross-bridge pattern (upper part) and the corresponding successive changes in the shape of a cilium (lower part) during a single beat cycle. There is striking similarity between the simulated and the actual beating forms shown in Fig. 2. The active sliding is localized in each pair of the doublets (Fig. 1). In a single pair of the doublets, the local activation starts at the basal end, travelling up along the doublets, then disappears at the tip. In the nine pairs of doublets, the activation is transmitted from one pair clockwise to the adjacent pair ($n \rightarrow n+1$). There is an exceptionally long interval between the start of activation in the 4–5 pair (pattern no. 37) and that in the 5–6 pair (pattern no. 15). This indicates that the cyclic activation of the dynein–tubulin cross-bridges originates in the 5–6 pair and terminates at the 4–5 pair. Initiation of activation in the 5–6 pair corresponds to the start of the recovery stroke. Therefore, we propose that in a single beat cycle the recovery stroke precedes the effective stroke, which is consistent with the observation that when cilia of *Paramecium* are inhibited by Ni^{2-} ions and stop, they assume a position which corresponds to the final position of the effective stroke[12–14]. Similarly, a large abfrontal cilium of *Mytilus* gill rests exclusively at the end of the effective stroke[15].

Our simulated patterns are consistent with the proposal of Satir and co-workers[7,16] that activation in the 6–9 doublets

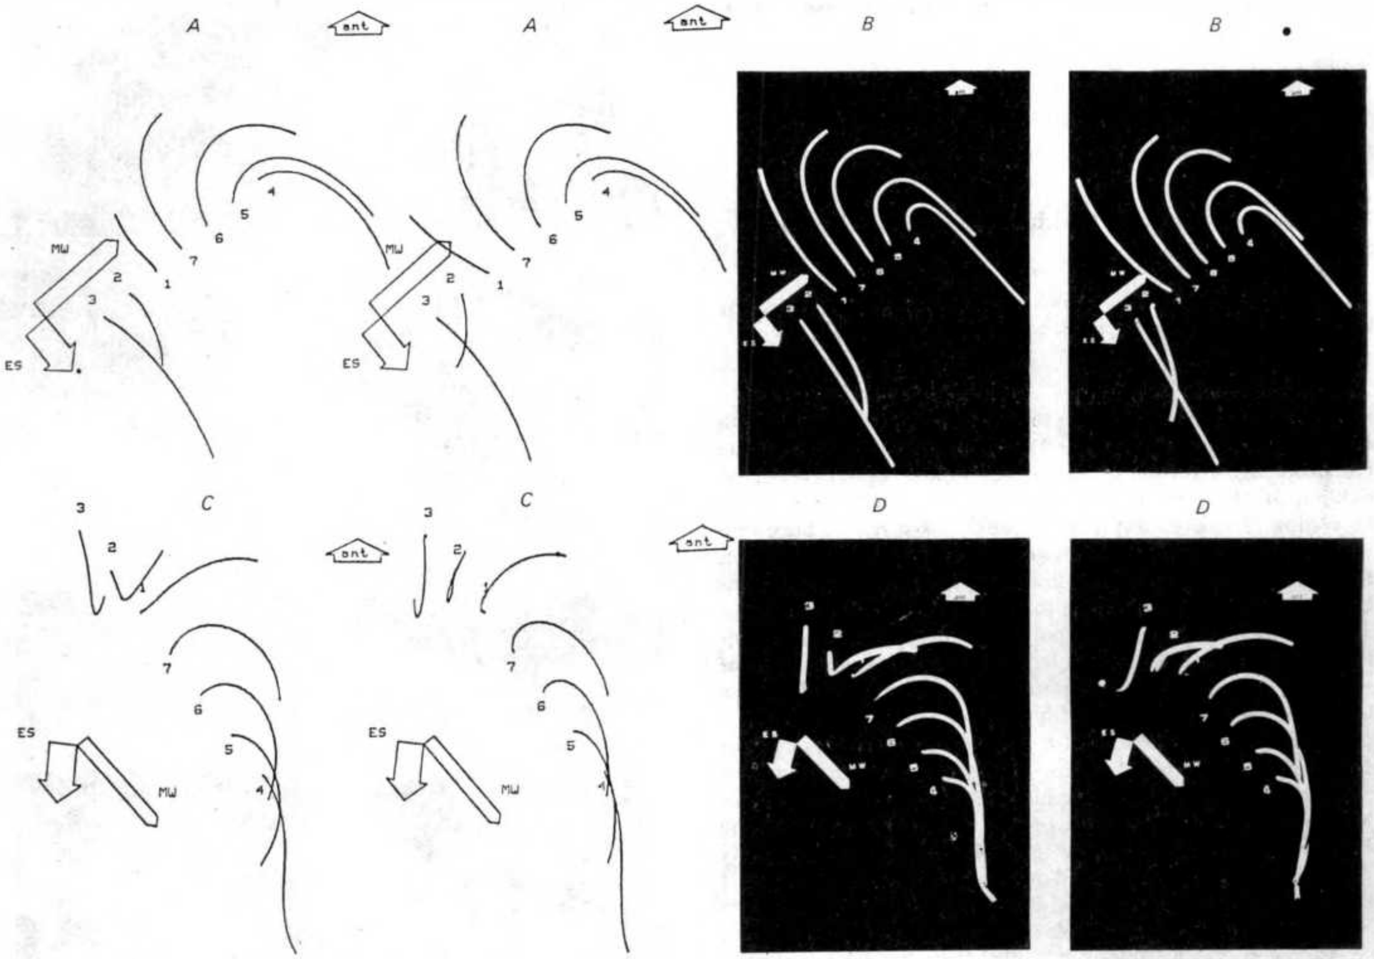

Fig. 2 Stereoscopic displays of seven successive changes in the shape of a cilium from *Paramecium* during a single beat cycle. *A*, *C*, stereoscopic display of computer-simulated beating forms. Each ciliary shape is simulated according to each cross-bridge pattern having corresponding numbers encircled in Fig. 1. Those on the left were viewed from just above, and those on the right were viewed 10° from the right. *B*, *D*, stereophotographs of metal wire models of cilia. Seven pieces of metal wire were shaped and arranged according to Machemer[20,21] based on his photographs of free-swimming *Paramecium*. The computer displays (*A* and *C*) also follow Machemer's arrangement of the wire models. *A*, *B*, beating forms in normal solution; *C*, *D*, beating forms in viscous medium (viscosity 40 times greater than that of normal solution). Arrows labelled 'ant' indicate the anterior end of *Paramecium*. Arrows labelled 'ES' indicate the direction in which the cilium points at the end of effective stroke. Arrows labelled 'MW' indicate the direction of movement of the metachronal wave of cilia. The seven successive ciliary shapes are aligned in the direction of the metachronal wave. Time interval between each successive ciliary shape was kept constant at 1/7 of the period of a single beat cycle.

corresponds to the recovery stroke, that in the 1–4 doublets to the effective stroke. A long time interval is also observed between activation in the 1–2 pair (pattern 23) and that in the 2–3 pair (pattern 32), although it is shorter than the activation time interval between the 4–5 pair and the 5–6 pair. These two time intervals in doublet activation observed in our simulated patterns, one at the start of the effective stroke and the other at the start of the recovery stroke, strongly suggest the presence of two switching mechanisms for the activation in a single beat cycle of a cilium, as suggested by Wais-Steider and Satir[16] based on inhibition experiments on mussel gill cilia by vanadate and calcium.

Note that when viscous restriction 40 times larger than that used for the simulation of the beating in normal medium was introduced into the model, the simulated form was strikingly similar to a cilium of *Paramecium* swimming in a medium of viscosity 40 times greater than that of normal medium (compare Fig. 2*C* with *D*). This strongly supports our idea that computer-estimated cross-bridge patterns closely resemble those of an actual cilium during beating. Computer-assisted estimation of the distribution of the actively sliding regions in a cilium may elucidate the molecular mechanisms underlying ciliary movement.

Parts of this work were presented at the 2nd IBS Symposium on cell motility (held in March 1980 at Okazaki, Japan) and at the 53rd annual meeting of the Zoological Society of Japan (October 1980, Shizuoka, Japan)[17]. The work was supported by the Mitsubishi Foundation and the Ministry of Education of Japan (Y.N.) (grants 144006, 411802, 411808, 510902, 511201). We thank Drs K. Nakayama, Y. Fujiwara, K. Ikeda and their colleagues in the Computer Center at the University of Tsukuba for discussions. We also thank Drs S. Ishizaka and R. Le Brasseur for reading the manuscript and Mrs K. Fujiwara for help with the graphic display.

Release of spectrin-free spicules on reoxygenation of sickled erythrocytes

David Allan, Anthony R. Limbrick*, Paul Thomas & Maxwell P. Westerman†

Department of Experimental Pathology, University College London, School of Medicine, University Street, London WC1E 6JJ, UK

It has long been suspected that the erythrocytes of patients with sickle cell disease gradually shed part of their plasma membrane either through a normal ageing process or as a result of repeated sickling, and that this membrane loss may be associated with the formation of irreversibly sickled cells[1–3]. We report here that when sickled HbS erythrocytes are unsickled by reoxygenation, the cells lose ~2–3% of their lipid as spectrin-free haeomoglobin-containing spicules in the form of rods and microspheres. The rods, which still contain polymerized haemoglobin, eventually degrade to chains of microvesicles having diameters of ~0.1 μm. Similar spicular material has been found in the untreated blood of patients with sickle cell disease.

Blood from patients with homozygous sickle cell disease was collected in heparinized tubes; red cells were sedimented at 2,000 r.p.m. for 5 min and the plasma was retained. Cells were washed four times with 10 vol of 0.15 M NaCl containing 10 mM HEPES–NaOH buffer *p*H 7.4, with removal of buffy coat. They were resuspended in the same medium to 10% haematocrit and deoxygenated by incubation at 37 °C under a N_2 atmosphere for 1 h. In these conditions, at least 90% of the cells showed the characteristic sickled form, with long spicules protruding from the cell surfaces (Fig. 1*a*). Cells were sedimented at 1,500 r.p.m. for 5 min and after removal of the supernatant, they were resuspended in the same volume of the original medium. Reoxygenation and restoration of the original diskoid shape of the cells (see Fig. 1*d*) was achieved by exposure to air for 30 min at 37 °C, then the cells were again sedimented at 1,500 r.p.m. for 5 min. The resulting opalescent supernatant was centrifuged at 16,000 r.p.m. for 10 min, giving a small red pellet, sometimes overlain by a filmy deposit of ghosts which was removed during aspiration of the supernatant. Cell lysis after reoxygenation was <1%. The red pellet was resuspended in 8 ml HEPES-buffered saline, centrifuged at 1,500 r.p.m. for 5 min to remove any contaminating cells, then sedimented again at 16,000 r.p.m. for 10 min. The final red pellet was resuspended in 0.5 ml HEPES-buffered saline and samples were taken for electron microscopy and polyacrylamide gel electrophoresis and for determination of lipid and haemoglobin.

Light and electron microscopy revealed that this material consisted largely of rod-like elements similar in size (up to 15 μm long) and shape to the spicules seen protruding from the original deoxygenated cells. The material released probably corresponded to the distal portions of the spicules on the original N_2-treated cells, as subsequent exposure of the reoxygenated cells to N_2 yielded cells with less extreme spiculation (Fig. 1*b*). However, in addition to the rod-like elements in the high-speed pellet, there were many spherical bodies of ~0.5 μm diameter. Some of this fraction evidently sedimented at lower speed than the rod-like spicules as it was present together with intact cells in a low-speed fraction derived from the original high-speed pellet (Fig. 1*d*). In some cases, it appeared that these small spherical components were still being released from the reoxygenated cells (arrows, Fig. 1*d*).

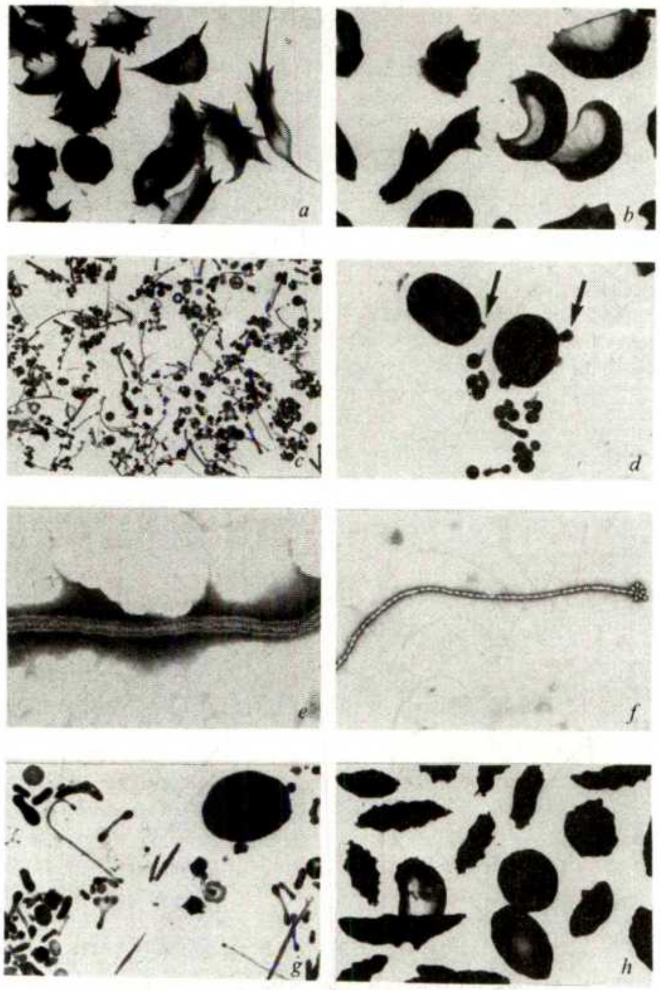

Fig. 1 Electron micrographs of sickle red cells and free spicules. *a*, Sickle cells incubated under N_2 for 1 h (×1,200). *b*, Sickle cells subjected to three doxygenation–oxygenation cycles, then reincubated under N_2 for 1 h (×1,200). *c*, Free spicules isolated after reoxygenation of deoxygenated sickle cells (purified fraction remaining after removal of fraction shown in *d*) (×1,200). *d*, Low-speed (1,500 r.p.m.) sediment from crude spicule fraction (×1,200). *e*, Rod-like spicule (×16,000). *f*, Free spicule after incubation of sample *c* at 20 °C for 2 h (×5,000). *g*, Free spicules isolated from plasma of patient P.R. with sickle cell disease. Fresh plasma was centrifuged at 16,000 r.p.m. for 10 min. The pellet was resuspended, decanted from clumped platelets and centrifuged again at 16,000*g* to give a small red pellet (×1,200). *h*, Red cells of patient R.E. with a high level (50%) of irreversibly sickled cells (×1,200). Specimens were fixed in 2% glutaraldehyde in 0.1 M cacodylate buffer *p*H 7.4 for 1 h then washed in buffer several times. For negative staining, a drop of the suspension of fixed specimen was placed on a carbon-coated copper grid and after 2 min, excess buffer was removed with filter paper. Samples were then stained for 2 min with 1% phosphotungstate, *p*H 7.0. Excess stain was removed with filter paper and the preparation was air-dried. All specimens were examined using a JEOL 100CX microscope.

The rod-like forms appeared under the light microscope to be rigid structures, suggesting that the sickle haemoglobin present within the rods was still in a polymerized form even after oxygenation. This interpretation was confirmed by electron microscopy of negatively-stained specimens which often showed an internal structure resembling a helical continuous filament ~30 nm thick and of ~120 nm pitch (Fig. 1*e*). These dimensions are consistent with those observed previously for the helical polymer of pure haemoglobin S[4]. After several hours at room temperature, it was apparent that the rod-like spicules became 'floppy' and tended to break down into chains of tiny vesicles with diameters of ~0.1 μm (Fig. 1*f*). There was then no visible

0028-0836/82/070612—02$01.00

evidence of internal structure, suggesting that the haemoglobin had finally depolymerized, perhaps thus allowing membrane fusion to occur along the length of the rods.

When cells were subjected to several cycles of deoxygenation–oxygenation, ~2–3% of the total cell phospholipid and 0.2–0.3% of the total haemoglobin were released as free spicules (Table 1). Incubation under N_2 alone released negligible amounts of material and 80–90% of the release occurred after the first reoxygenation. Neither N_2 treatment nor reoxygenation produced a significant change in cell volume. No measurable release was observed from normal (HbA) erythrocytes which were treated similarly. Release of free spicules from sickle erythrocytes was unaffected by incubation in medium to which was added either 10 mM glucose, 5 mM iodoacetamide and 1 mM deoxyglucose (which reduced intracellular ATP to <10% of normal), 1 mM Ca^{2+} or 1 mM EGTA, or by substitution of autologous plasma for the normal HEPES-buffered saline medium. Incubation in the presence of protease inhibitors (diisopropylfluorophosphate, TLCK) did not alter the production of free spicules.

Figure 2 and Table 1 demonstrate that the composition of the released material resembles that of microvesicles released from normal cells aged *in vitro*[5,6] or treated with Ca^{2+} ionophore[7–9], and from sickle cells incubated *in vitro* with Ca^{2+} or EGTA.[3] No reproducible differences in lipid composition were observed between the free spicules and the cells themselves.

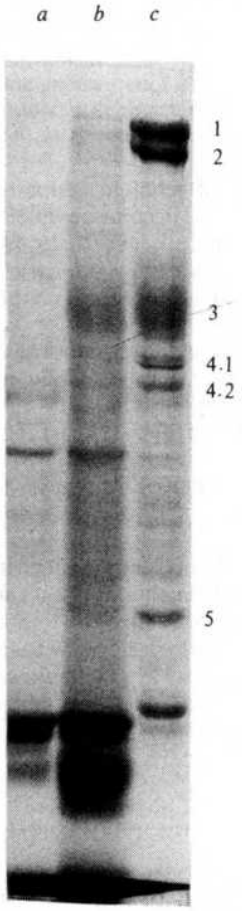

Fig. 2 Polyacrylamide gel electrophoresis of cell fractions. Cytosol (*a*) and membranes (*c*) from sickle cells were prepared as described previously[3]. Free spicular material (*b*) was prepared as described in the text. Samples containing ~20 nmol phospholipid (membranes and spicules) or 500 μg protein (cytosolic fraction) were analysed by polyacrylamide gel electrophoresis on 7.5% gels[15]. Gels were stained with Coomassie blue. Bands are numbered according to the nomenclature of Steck[16].

Table 1 Composition of sickle cells and of free spicules •

	Cells	Free spicules produced by reoxygenation or anerobic cells	Free spicules from plasma (determinations on two patients)
Phospholipid (nmol per mg haemoglobin)	19±1 (10)	233±43 (12)	179, 210
Cholesterol (mol per mol phospholipid	0.70±0.06 (29)	0.53±0.14 (17)	0.51, 057
Acetylcholinesterase activity (μmol min^{-1} per μmol phospholipid)	4.3±1.0 (20)	3.6±1.2 (6)	3.0, 2.5

The mean yield of free spicules produced *in vitro* was 2.3±0.4% (5) of the total red cell lipid. The yield of spicules *in vivo* (plasma) was 0.5±0.2% (3) of total red cell lipid in a given volume of blood. Results are derived from studies of 12 patients and are expressed as mean±s.d. Number of determinations is shown in parentheses. Assays were carried out as in ref. 9.

The most striking feature of the free spicules was their almost complete lack of the membrane cytoskeletal polypeptides spectrin (bands 1, 2), ankyrin (band 2.1), band 4.1 and actin (band 5). This implies that the spicules observed on the cells before reoxygenation similarly lacked these cytoskeletal proteins and that the spicules were produced by polymerization of HbS through gaps in the actin–spectrin framework, causing a herniation of the lipid bilayer part of the membrane only. Release of the rod-like spicules following reoxygenation may depend on the failure of HbS in the spicules to depolymerize (perhaps because of its close association with membrane[10,11]) in conditions where HbS in the cell body does depolymerize, allowing membrane fusion to occur only around the 'necks' of the spicules.

Loss of spicules from sickle cells may also occur during the deoxygenation–oxygenation cycling which occurs naturally *in vivo*, as spicular material similar to that prepared *in vitro* has been found in the untreated plasma of sickle cell patients (Fig. 1*g*) but is completely absent from the blood of normal individuals. The composition of this material resembled that of the free spicules *in vitro* (Table 1) and the yield was equivalent to ~0.5% of the total red cell lipid in a given volume of blood.

The clinical significance and eventual fate of the *in vivo* spicules is unknown, but it seems possible that these particles, particularly those with rigid rod-like structures, might contribute to the vaso-occlusive events associated with sickle cell disease[12]. Loss of spicular material from sickle cells *in vivo* may also contribute to the production of irreversibly sickled cells, which appear to have reduced membrane content[13] and show much less surface spiculation than do reversibly sickled cells[14] (Fig. 1*h*). Preliminary data suggest that patients with higher levels of irreversibly sickled cells also have more free spicules in their plasma.

M.P.W. was the recipient of a Research Travel Grant from the Burroughs Wellcome Fund. We thank Professors E. J. Huehns and J. M. White for providing samples of blood from their patients. We also thank the MRC for supporting this work.

A non-collagenous glycoprotein from elastic tissue acts as substratum for growth of cells *in vitro*

***In vivo*, cells are in intimate contact with an extracellular matrix, one of the components of which is collagen; the adhesion of cells to collagen *in vitro* has been extensively studied (for review, see ref. 1). In several connective tissue matrices, collagen fibres are replaced to a variable extent by elastin fibres which, under the electron microscope, appear to be composed of an elastin core surrounded by a network of fibrils ~11 nm in diameter, usually referred to as the microfibrillin component. These fibrils have been implicated, on morphological grounds, in the biosynthesis of elastin fibres. A glycoprotein referred to as structural glycoprotein (SGP)[2], which has a molecular weight (*M_r*) of 34,000 and aggregates to form cylindrical tactoids having a uniform diameter of 11 nm, has been isolated from bovine ligamentum nuchae[3]. SGP was found to have amine oxidase activity, thus it seems to be functionally related to other peptidylysine oxidases involved in the biosynthesis of the elastin cross-links[4–6]. Here we show that SGP acts as a substratum for fibroblasts and other cell types with fibronectin mediating the attachment and spreading of the cells. These results suggest that SGP may have a role in wound healing, morphogenetic movement and development of elastic tissues.**

SGP was isolated from ligamentum nuchae as described elsewhere[2]. Briefly, the microfibrils found in elastic tissue were dissociated by treatment with 5 M guanidine HCl containing a disulphide bond reducing agent[3], and purified by preparative gel electrophoresis[2]. In the absence of chaotropic and reducing agents, and in the presence of Cu^{2+} ions, the purified SGP aggregates as described previously[2]. We have used this property to prepare SGP aggregates for assays of cell adhesion and growth *in vitro*. This was achieved by forming discrete areas of aggregated SGP by precipitation on to bacteriological grade Petri dishes. The dishes are made of untreated polystyrene with negligible surface charge and as already described[7] have only a limited capacity to support cell adhesion. Using a single Petri dish it is therefore possible to compare cell attachment, spreading and proliferation of cells on an SGP substratum with that on areas of untreated polystyrene.

When an established cell line BHK 21 was subcultured on to these Petri dishes, the cells attached and spread rapidly on the SGP. In contrast, there was little attachment to the untreated polystyrene, and after 6 h no spreading had occurred. Figure 1 shows the kinetics of attachment and spreading. Cells on the SGP areas proliferate and become completely confluent. On the untreated areas, some cells eventually assume a fibroblastic morphology, but most cells grow as loose clumps[7]. After 2 days, little or no proliferation had occurred on the untreated surfaces.

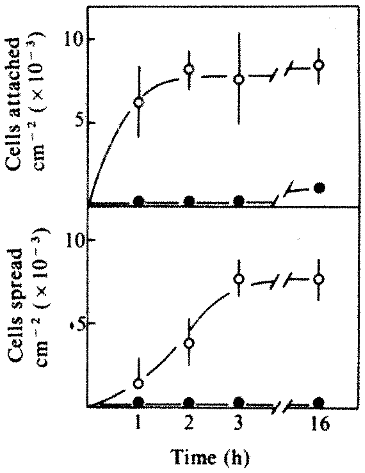

Fig. 1 Attachment and spreading of cells on SGP. Petri dishes containing SGP spots were prepared as follows: purified SGP was dissolved under nitrogen in 8 M urea containing 3% mercaptoethanol. Several 6-µl droplets of this solution were placed on bacteriological grade Petri dishes (three or four spots per dish) to which were immediately added 6-µl drops of copper sulphate solution providing a 400 M excess of Cu^{2+} ions. The Petri dishes were dried over P_2O_5 *in vacuo* for 24 h, then washed exhaustively with distilled water and finally dried. Confluent cultures of BHK 21 cells (Flow) were trypsinized (0.05% trypsin/0.02% EDTA; Flow) and resuspended at a density of 5×10^4 ml^{-1} in Ham's F10 medium supplemented with 7.5% newborn calf serum (Flow). Cell suspension (10 ml) was poured into each Petri dish containing SGP spots and then incubated at 37 °C in a humidified 5% CO_2 atmosphere. At intervals the dishes were examined using an inverted microscope. The numbers of attached and/or spread cells were counted for six random areas of SGP substrata (○) and control polystyrene substrata (●). The criteria for spreading are that a cell exhibits polarity and the nucleus and nucleoli are clearly visible. Results are expressed as the mean ± s.d. for the six areas.

We have tested other proteins for activity as substrata. Albumin, fibrinogen, γ-globulin and ovalbumin do not support attachment when they are either dried on to bacteriological polystyrene or precipitated with Cu^{2+} or Cu^{2+} plus mercaptoethanol. The only proteins, apart from SGP, that are completely effective as substrata are collagen or fibrin. Fibronectin is only partially effective on bacteriological polystyrene; possibly the low surface charge does not allow suitable binding of the glycoprotein.

The technique used for coating bacteriological plastic with SGP is only suitable for smaller areas; it cannot be used to coat whole Petri dishes. To determine the total number of cells able to attach to SGP, bacteriological plastic coated with SGP was cut into circles that would just fit into multiwell plates, and these

Table 1 Fibronectin mediates cell attachment and spreading on SGP

	Cells attached per cm^2 $\times 10^{-3}$				Cells spread per per cm^2 $\times 10^{-3}$			
	Native polystyrene	Tissue culture plastic	Collagen	SGP	Native polystyrene	Tissue culture plastic	Collagen	SGP
No protein	0	9.8 ± 0.1	3.2 ± 1.7	2.0 ± 0.7	0	0	0	0
Newborn calf serum (1%)	0	9.5 ± 1.6	8.6 ± 1.9	9.3 ± 2.1	0	9.3 ± 2.2	8.1 ± 0.9	8.9 ± 2.7
Fibronectin (25 µg ml^{-1})	0.6 ± 0.4	10.0 ± 1.2	9.4 ± 2.4	9.6 ± 1.8	0	9.8 ± 1.1	8.9 ± 0.9	9.6 ± 1.6

Fibronectin was prepared from fresh human plasma as described elsewhere[14], but using chaotropic elution buffers[15]. BHK cells were suspended as described in Fig. 1 legend in Ham's F10 medium containing 1% newborn calf serum or 25 µg ml^{-1} fibronectin, or no protein supplement. Cell suspensions were poured into bacteriological grade Petri dishes containing SGP spots and incubated at 37 °C for 4 h. At this time cell attachment and spreading on SGP was assessed as described in Fig. 1 legend.

0028-0836/82/070614—02$01.00

were secured in place with Araldite. BHK cell suspensions were poured into the multiwells and it was found that >96% of cells were able to adhere to the SGP.

Primary cultures derived from chick embryo also proliferate on SGP; Fig. 2*a* shows a Petri dish fixed and stained at 72 h. The SGP spots were clearly visible because of the high cell density in these areas. The spots have discrete edges and cells appear to remain on the SGP rather than migrate on to areas of untreated polystyrene. Harris[8] has previously shown that cells will preferentially migrate on to areas of suitable charge density. Figure 2*b* shows cells at the edge of an SGP spot.

We have repeated these experiments and found that various cell types including 3T3 and a virally transformed derivative, a human osteosarcoma cell line, human skin fibroblasts and primary cultures derived from neonatal rat all attach to and proliferate on SGP, but not on untreated polystyrene. Compared with established cell lines, primary cell cultures display a more fastidious requirement for a suitable substratum. Thus some epithelial cells show a specific requirement for collagen type IV[1]. Similarly, myogenic cultures will only differentiate on layers of collagen (or gelatin)[9]; in this case the collagen seems to aid alignment of myoblasts before their fusion to form multinucleate myotubes. We derived cell suspensions from embryonic chicken muscle and plated these on to Petri dishes containing discrete spots of SGP. When the cultures were fixed and stained 4 days later, cells were found only on the SGP spots. Multinucleate myotubes were present but were located only on the upper surfaces of other cells, presumably fibroblasts. The morphology of these cultures is in marked contrast to control cultures grown on collagen, where myotubes were found in the monolayer. Cultures grown on tissue culture plastic showed few myotubes and all cells were present as a monolayer. Myogenic cultures consist predominantly of fibroblasts and myoblasts. The above results indicate that fibroblasts adhere to SGP but myoblasts cannot. However, fibroblasts synthesize collagen and it is to this substrate that the myoblasts adhere and on which they subsequently differentiate. This explains why the cultures were bilayers rather than monolayers, and why the myotubes were found almost exclusively in the upper layer. In contrast to these cultures on SGP, both myoblasts and fibroblasts adhere to collagen or to tissue culture plastic, and hence in both cases only monolayer cultures result.

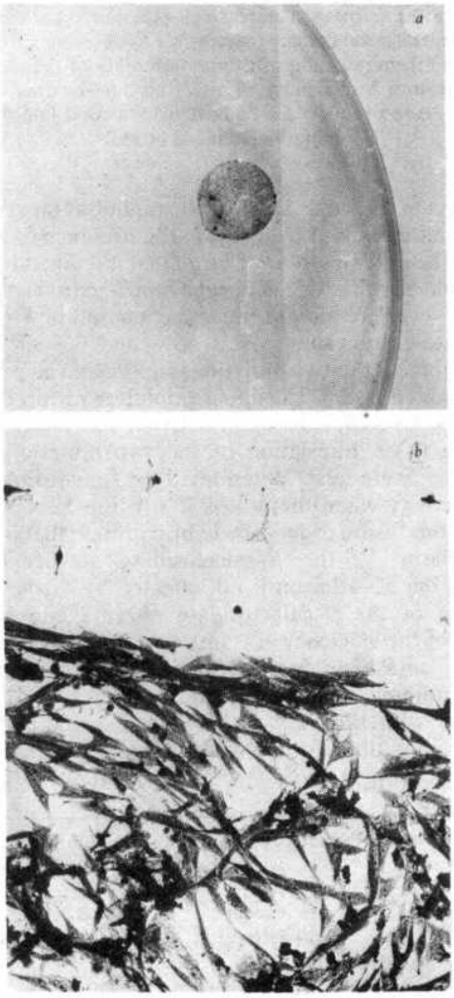

Fig. 2 Primary cultures on SGP substrata. Cell suspensions were derived from chick embryos as described elsewhere[16], and suspended at a density of 10^5 cells ml^{-1} in Ham's F10 medium containing 10% fetal calf serum (Flow). Cells were plated in bacteriological grade Petri dishes containing SGP spots and incubated at 37 °C in a humidified 5% CO_2 atmosphere. Cultures were refed after 24 h, then incubated for a further 48 h. Dishes were then rinsed with phosphate-buffered saline, fixed with 3% glutaraldehyde and stained with 1% filtered Giemsa. *a*, SGP spots are clearly visible because of the density of cells staining with Giemsa. *b*, Photomicrograph showing cells forming a discrete boundary at the edge of a SGP spot. ×70.

Cells require specific proteins for their attachment to a substratum. We have investigated the requirement for adhesion to SGP using fibronectin prepared from human plasma. Table 1 shows the attachment and spreading of cells in the presence and absence of fibronectin on SGP, collagen and tissue culture or bacteriological grade plastic. It is clear that fibronectin is able to mediate spreading on SGP surfaces, the concentration of fibronectin necessary to promote maximal attachment to SGP or to collagen being $<1\ \mu g\ ml^{-1}$. However, to achieve maximal spreading, according to our criteria, the concentration has to be $>5\ \mu g\ ml^{-1}$.

We have demonstrated that the microfibrillary glycoprotein referred to as SGP acts as a solid substratum *in vitro* and supports the attachment, spreading and growth of various cell types. Certain synthetic agents including tissue culture plastic, glass[10] and resins[11] also have this property. However, SGP is a physiological glycoprotein and it is therefore possible that, like collagen, and to a lesser extent fibrin, there is a physiological role for this adhesive property. We, and others[12] have shown that other proteins do not act as suitable substrata for cell adhesion and growth. The adhesion of cells to SGP is clearly analogous to that of the attachment of cells to collagen[1], and indeed to fibrin[13]. In all these cases fibronectin appears to mediate at least part of the adhesive process. (This in contrast to the attachment of epithelial cells to collagen type IV which is mediated by laminin[1].)

Microfibrillary SGP is particularly abundant during fetal development[14], thus it is possible that SGP may, by providing a pathway for morphogenetic movement, play a part in the genesis of vascular and other tissues requiring an elastic stroma. During wound repair of vascular tissue, SGP may also have a role in directing the movement of endothelial fibroblasts.

It has been suggested that SGP plays a part in the elaboration of elastin and we are now investigating the possibility that the adhesion of certain fibroblasts to SGP in some way acts as a signal for elastin synthesis.

We thank Mrs Salma Siddiqui and Miss Sheila Griffiths for technical assistance.

A role for mRNA secondary structure in the control of translation initiation

Michael N. Hall*, Joëlle Gabay, Michel Débarbouillé & Maxime Schwartz

Unité de Génétique Moléculaire, Institut Pasteur, 25 rue du Dr Roux, 75724 Paris Cedex 15, France

A role for messenger RNA (mRNA) secondary structure in the control of translation initiation has been assumed for many years[1-3]. Strong additional evidence supporting this notion is now provided by work on the *lamB* gene of *Escherichia coli*, which codes for a major outer membrane protein that functions both as a receptor for phages λ, K-10 and TP1, and as a component of the maltose and maltodextrin transport system[4-9]. Mutations that affect translation initiation of the *lamB* mRNA have been described previously[10]. DNA sequence analysis indicated that one such mutation, *lamB* 701, is located two nucleotides promoter-proximal to the *lamB* Shine–Dalgarno sequence. A second mutation, *lamB* 708, is located in the sixth codon of the *lamB* gene (see Fig. 1). Schwartz *et al.*[10] suggested that these two point mutations affect translation initiation by favouring the formation of a base-paired hairpin structure in the *lamB* transcript which makes the Shine–Dalgarno sequence[11] inaccessible to ribosomes (see Fig. 2). This suggestion was genetically testable because it predicted that the translation initiation defect caused by either of the two mutations alone would be suppressed in a *lamB* 701–708 double mutant (see Fig. 2). Here we demonstrate that the 701 and 708 mutations do indeed suppress each other, as predicted by an effect attributable to mRNA secondary structure.

The 701–708 double mutant was constructed *in vivo* by homologous recombination within the 26 base pairs (bp) that separate the two mutations. The strategy used in this construction, described in Fig. 3 legend, involved three steps. First, a λ transducing phage carrying the *lamB–lacZ* hybrid gene 52–4 (refs 12, 13) containing the 701 mutation (Fig. 3*a*) was constructed. This phage was then used to lysogenize a strain containing the 708 mutation such that the integrative recombination event occurred between the sites of the two mutations. The last step consisted of curing the prophage, the cured strain containing both 701 and 708 *cis* to an otherwise wild-type *lamB* gene. The eventual double mutation construct (Fig. 3*c*) was verified by DNA sequence analysis using the Maxam–Gilbert method[14,15].

The effects of 701 and 708, individually and in combination, were measured by two independent methods (Table 1). One consisted of assaying λ receptor protein present in the outer membrane of the single and double mutants. The second method exploited the availability of *lamB–lacZ* hybrid genes to measure translational activity initiated at the *lamB* initiation codon.

Fig. 1 The *lamB* mRNA Shine–Dalgarno and surrounding sequences. The Shine–Dalgarno sequence is underlined. The nucleotide changes resulting from the 701 and 708 mutations are indicated. The 708 mutation causes an arginine to serine change in the sixth codon of the *lamB* gene. The *lamB* gene is the promoter-distal gene of the maltose-inducible *malK–lamB* operon.

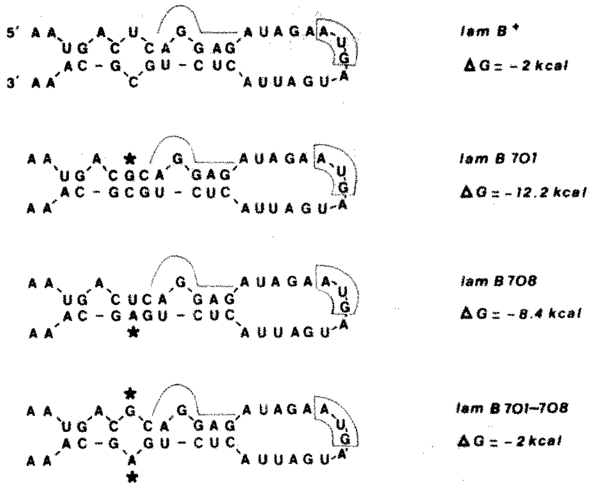

Fig. 2 Possible hairpin structure and corresponding thermodynamic stabilities of *lamB* mRNA containing a wild-type sequence, the 701 mutation, the 708 mutation or the 701–708 double mutation. The thermodynamic stabilities are calculated according to Tinoco *et al.*[26], and are expressed as the free energy (ΔG) of the structure. The two single mutations thermodynamically favour the hairpin structure which would be assumed to render the Shine–Dalgarno domain inaccessible to ribosomes. The double mutation regenerates the wild-type instability of the hairpin and should restore accessibility of the ribosome-binding site. The Shine-Dalgarno sequence is indicated by a solid line; the *lamB* initiation codon is boxed.

The effect of the single and double mutations on gene expression was first measured by assaying the presence of λ receptor activity in the outer membrane of cells containing the mutations of interest in an otherwise wild-type *lamB* gene. The mutations individually were found to reduce the amount of λ receptor to approximately equivalent levels—5% and 8% of wild type. When combined, the two mutations suppressed each other, but only to a limited extent. The double mutation restored only 25% of wild-type levels of λ receptor activity.

The effects on translation of the two mutations and the combination were also determined by measuring β-galactosidase activity when these were *cis* to the 52-4 *lamB–lacZ* fusion. As this fusion codes for a hybrid protein that is located in the cytoplasm[12,13], the β-galactosidase activity of strains containing the 52-4 fusion is not affected by extracytoplasmic localization of the β-galactosidase enzyme and is a direct indication of the efficiency of translation initiating at the beginning of the *lamB* gene. In the case of 701 and 708 individually, strains containing either one of the two mutant alleles were lysogenized with the 52-4 fusion phage containing the corresponding mutation. For the wild-type control, a *lamB*$^+$ strain was lysogenized with a wild-type 52-4 fusion phage. In the case

Table 1 Effect of mutations 701 and 708, individually and combined, on *lamB* expression.

	% λ receptor activity	% β-galactosidase activity
lamB$^+$	100	100
lamB 701	8	4
lamB 708	5	28
lamB 701–708	25	81

Values are expressed as per cent of wild type. The λ receptor value indicates the effect of mutation in an otherwise wild-type *lamB* gene; β-galactosidase value indicates effect of mutation when *cis* to a *lamB–lacZ* hybrid gene. The λ receptor activity was assayed as described previously[4,24] with the following modifications. Outer membranes were solubilized in 10 mM Tris-HCl *p*H 7.5, 5 mM EDTA, 3% Triton X-100 and incubated for 1 h at 37 °C. Phage λ inactivating ability was then assayed directly, and β-galactosidase activity was assayed as described elsewhere[25].

of the double mutation, an appropriate strain was constructed (Fig. 4). In contrast to the results obtained by measuring λ receptor activity, showing a similar effect of 701 and 708 individually and a low level of suppression in the double mutant, β-galactosidase assays indicated that the effects of 701 and 708 individually are quantitatively different, 708 being significantly more leaky than 701. Essentially full suppression is observed in the 701–708 double mutant.

These results indicate three facts. (1) The 701 and 708 mutations do indeed suppress each other, suggesting that their effect is attributable to mRNA secondary structure (see Fig. 2). (2) The relative effects of the two mutations on translation initiation can be correlated with their effect on the thermodynamic stability of the predicted mRNA secondary structure. (3) The phenotype of a strain containing the 708 mutation in an otherwise wild-type *lamB* gene is a superimposition of defects in both translation initiation of the *lamB* message and localization of the *lamB* gene product to the outer membrane.

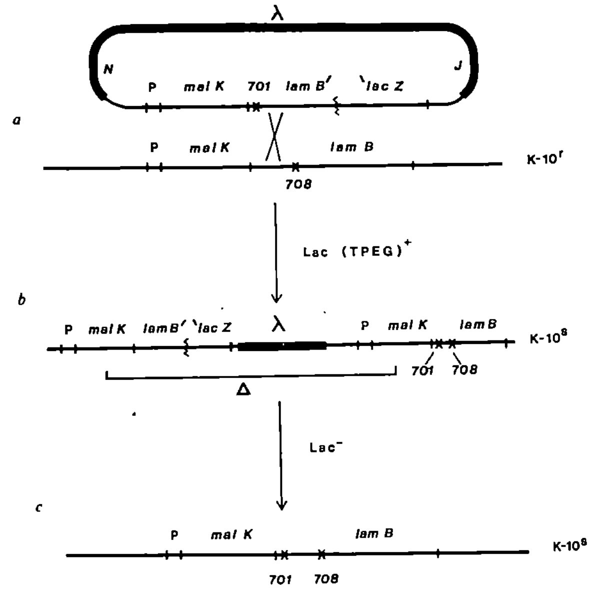

Fig. 3 Construction of the 701–708 double mutant, *in vivo*, by homologous recombination between the 701 and 708 mutations. A λ transducing phage carrying the 701 mutation recombined into the *lamB* portion of the 52-4 *lamB–lacZ* gene fusion was first constructed. The 52-4 fusion codes for a hybrid protein consisting of the NH_2-terminal 39 amino acids from LamB (including the signal sequence) and a COOH terminus of active β-galactosidase[12]. Expression of β-galactosidase activity by the 52-4 hybrid gene relies on translation initiated at the *lamB* initiation codon. The 701 and 708 mutations both reduce initiation of translation of a *lamB* transcript such that these confer resistance to phage K-10 (K-10ʳ) when *cis* to a wild-type *lamB* gene or elicit low levels of β-galactosidase activity when *cis* to a *lamB–lacZ* fusion. To recombine the 701 mutation into the 52-4 hybrid gene, the λ transducing phage carrying this gene was used to infect a *lamB* 701 strain. A phage carrying both the 701 mutation and the fusion was subsequently obtained by plating on Lac indicator media and a Lac⁻ host, the phage being spontaneously released from the resultant lysogen. The desired phage was detected by a Lac⁻ plaque phenotype. *a*, The transducing phage bearing the 52-4 fusion and the 701 mutation was used to infect the 708 mutant. *a*, *b*, A Lac⁺ phenotype in the presence of 10^{-3} M phenylethyl-β-D-thiogalactoside (TPEG) was selected. TPEG, a competitive inhibitor of β-galactosidase[27], was required to increase the stringency of the leaky Lac⁻ phenotype conferred by the 701 and 708 mutations when *cis* to the 52-4 *lamB–lacZ* fusion. A Lac⁺ selection stipulated integration of the phage such that a wild-type sequence was generated *cis* to the fusion, placing the 701 and 708 mutations *cis* to the wild-type *lamB* gene. This scheme avoided exerting selective pressure on the gene bearing the double mutation. Assuming that the K-10 resistant phenotype of either one of the single mutants would be suppressed in the double mutant, Lac⁺ colonies were picked and screened for sensitivity to the phage K-10. K-10ˢ strains were obtained. *c*, A K-10ˢ Lac⁺ lysogen was cured of the prophage. Spontaneous loss of the prophage was detected by a Lac⁻ phenotype. 'P' indicates the promoter of the *malK–lamB* operon. Primes, as in *lamB'* or *lacZ*, indicate that the DNA for the genetic region referred to is deleted on the side the prime is written.

The 701–708 double mutation was constructed and placed *cis* to a *lamB–lacZ* fusion, thereby allowing direct determination of the effect of the combined mutations on *lamB* translation. The observed suppression of 701 and 708 by each other argues strongly that mRNA conformation does have a role in the effect of these two mutations on translation initiation.

The levels of β-galactosidase activity in strains containing the 701 and 708 mutations individually *cis* to a *lamB–lacZ* fusion indicate that whereas the 701 mutation reduces *lamB* translation to 4% of wild type, 708 reduces it to only 28%. This difference is consistent with the different predicted thermodynamic stabilities of the *lamB* mRNA hairpin structure in strains containing one of these mutations (see Fig. 2). Whereas the 701 mutation creates a G-C pairing in the hairpin stem, the 708 mutation creates a less stable U-A pairing. The relatively leaky effect of the 708 mutation can therefore be explained by a less stable hairpin structure and a consequently more accessible ribosome-binding site. This provides additional evidence that mRNA conformation can control relative levels of translational expression, which is particularly relevant to situations where proteins are known to be produced in vastly different amounts from a single transcript, such as in the case of the λ morphogenetic proteins[16–18].

The amount of λ receptor present in the outer membrane of strains containing either the 708 mutation or the 701–708 double mutation is much less than that predicted by the effect of these mutations on translational initiation as measured by β-galactosidase assays (see Table 1). This discrepancy can be explained by the fact that the 708 mutation has two effects: it not only allows base-pairing to occur, thereby affecting translation initiation as described above, but it also creates an arginine to serine change at the sixth position of the λ receptor signal sequence. We believe that this alteration of a charged amino acid to a neutral residue in the early hydrophilic portion of the signal sequence[19] reduces localization of the λ receptor protein to the outer membrane. The amount of λ receptor activity in the outer membrane therefore reflects a compound effect of the 708 mutation whereas cytoplasmic β-galactosidase activity reflects only the effect on translation initiation. The 701 mutation, which resides outside the *lamB* structural gene, has a similar effect as measured by either β-galactosidase or receptor activity. The 708 alteration in the early hydrophilic portion of the λ receptor

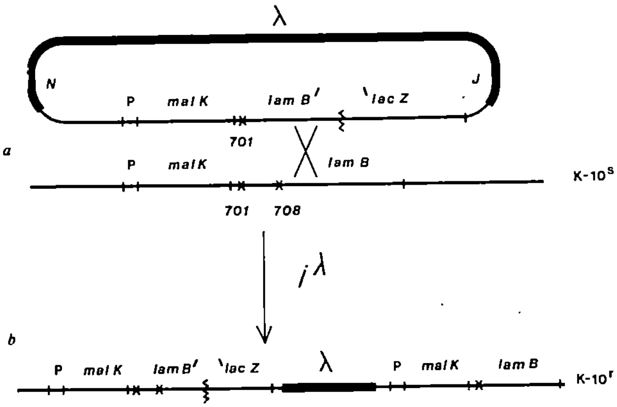

Fig. 4 Construction of strain for assaying suppression of translation initiation defect. *a*, The λ transducing phage carrying the 52-4 *lamB–lacZ* fusion containing the 701 mutation was used to infect the 701–708 mutant. Lysogens were selected by λ immunity. *b*, Integration of the transducing phage such that the double mutation was located *cis* to the *lamB–lacZ* fusion placed the 701 mutation *cis* to the otherwise wild-type *lamB* gene. The resultant strain was resistant to phage K-10, and was detected as such. The level of translation initiated at the *lamB* initiation codon flanked by the 701 and 708 mutations was determined by assay of *lacZ* expression—β-galactosidase activity.

signal sequence is a novel type of signal sequence mutation[20-22]. The unique properties of this signal sequence mutation in protein localization are described elsewhere (ref. 23 and M.N.H., M.D., J.G. and M.S., in preparation).

We thank Agnès Ullmann for suggesting use of phenylethyl-β-D-thiogalactoside, and Olivier Raibaud for helpful discussions. This work was supported by grants from the CNRS (LA 270) and DGRST (80-70182). M.N.H. was the recipient of an ADIP Fellowship from the Institut Pasteur.

Partial sequence of 16S ribosomal RNA and the phylogeny of *Prochloron*

Elke Seewaldt & Erko Stackebrandt

Lehrstuhl für Mikrobiologie, Technische Universität München,
Arcisstrasse 21, 8000 München 2, FRG

***Prochloron*, a symbiont of colonial ascidians, is a unicellular prokaryote, containing chlorophylls *a* and *b* and lacking phycobiliproteins[1], thus differing from all other prokaryotes found, and resembling the chloroplasts of Euglenaphyceae, Chlorophyceae and those of higher plants in respect of their photosynthetic pigments. Some workers in the field of endosymbiosis already favour the idea that the green algal chloroplasts may have arisen by the uptake of prochlorons as symbionts[2-5]. Partial sequence analysis of 16S ribosomal RNA of *Prochloron* in fact assigns this organism to the cyanobacteria-chloroplast line of descent[6-8]. However, we report here that a comparison of 16S ribosomal RNA sequences detects no specific relationship between *Prochloron* and the chloroplasts of the green algae *Euglena gracilis* and *Chlamydomonas reinhardii*, nor between *Prochloron* and the chloroplasts of higher plants, represented by *Lemna* and *Zea mays*. On the contrary, *Prochloron* shows the highest sequence homology with *Nostoc*, *Fischerella*, *Agmenellum*, *Aphanocapsa* and *Synechococcus*. These results question the significance of *Prochloron* in the current view of the origin of chloroplasts.**

All attempts to date to cultivate *Prochloron* in the laboratory have failed[9]. To study *Prochloron*, it is therefore necessary either to work with freeze-dried material collected in the field, or to isolate the molecule of choice in the field. Because previous attempts to isolate 16S rRNA from freeze-dried material were unsuccessful, one of us (E.St.) joined the 6th International Prochlorophyta Expedition to Palau, Micronesia. *Prochloron* was isolated from its host animal, *Lissoclinum patella*, simply by squeezing the host colonies, and its identity checked microscopically and by the photospectroscopic determination of chlorophylls *a* and *b* in acetone extracts. Samples of *Prochloron* were found to be free of host cells and bacterial contamination, a fact proved later by a clean 16S rRNA oligonucleotide fingerprint.

The ribonuclease T_1-resistant oligonucleotides of *Prochloron* ribosomal 16S RNA were then investigated by the method introduced by Woese and collaborators[10]. For the isolation of the RNA, cells were opened by French Press, the lysate was phenolized and the nucleic acids separated by one-dimensional polyacrylamide gel electrophoresis. Sequencing involved the digestion of the 16S rRNA by RNase T_1, dephosphorylation of 5′-terminated phosphates, *in vitro* labelling of the oligonucleotides with [γ-^{32}P]ATP and polynucleotide kinase, and resolution of the labelled fragments in two dimensions using a combination of high-voltage electrophoresis and gradient TLC[11]. The sequences of the isolated oligonucleotides ($\geq$6 nucleotides) were determined by controlled alkali cleavage, followed by separation of the products by combined high-voltage electrophoresis and homochromatography[11]. Table 1 shows the oligonucleotides $\geq$6 nucleotides long of the *Prochloron* 16S rRNA. Also indicated are any oligonucleotides of identical sequence found in the catalogues of various cyanobacteria and chloroplasts characterized previously, such as *Nostoc* (strain MAC)[6,12], *Fischerella ambigua*[6,12], *Agmenellum quadruplicatum*[6], *Synechococcus* strains 6301[6,13] and 7502[6], *Aphanocapsa* strains 6701 and 6714[6,14], and the chloroplasts of *Porphyridium creuntum*[6,15], *Z. mays*[16], *E. gracilis* strain Z[6,17] and *C. reinhardii* strain II/32–90 (our unpublished data).

Prochloron 16S rRNA has most oligonucleotides in common with *Agmenellum* (37), *Nostoc* (34), *Fischerella* (35) and *Aphanocapsa* (31 with strain 6701 and 32 with strain 6714). *Prochloron* and *Synechococcus* strains 7502 and 6301 are found to have 26 and 25, respectively, in common. The chloroplasts of *Porphyridium* and *Zea* have, respectively, 26 and 24 fragments in common with *Prochloron*, while *Prochloron* shares only 18 and 16 fragments with the chloroplasts of *Chlamydomonas* and *Euglena*, respectively.

The binary matching coefficients (S_{AB}) give a more detailed picture of the overall similarity between the catalogues of two organisms, because the total number of common nucleotides in all identical fragments is used to calculate relatedness between organisms. Table 2 shows the S_{AB} values of all pairwise comparisons between any two RNAs *A* and *B*. Figure 1 is a dendrogram of the relationship derived by average linkage clustering among the merged groups. S_{AB} values for *Prochloron*

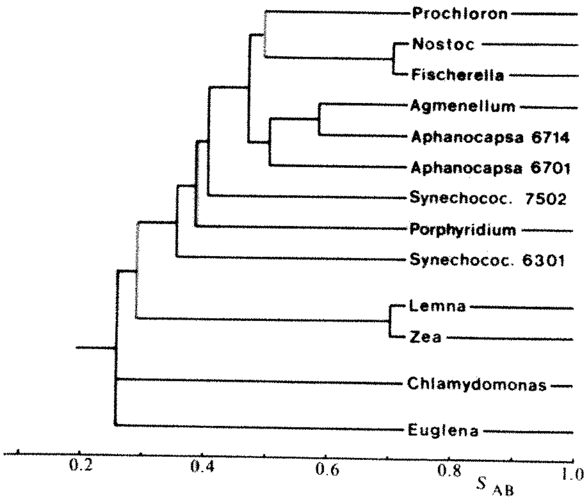

Fig. 1 Dendrogram of relationship, derived by average linkage clustering using a Dice-type similarity coefficient[20].

The table lists the oligonucleotide sequences in the 16S rRNA of *Prochloron* from *L. patella* and indicates which of these are also present in the 16S RNAs from cyanobacteria[6,12–14] and the 16S chloroplast rRNAs from *Porphyridium*[6,15], *Euglena*[6,17], *C. reinhardii* and *Z. mays*[16]. The catalogues of the 16S rRNA of *Lemna* and *Chlamydomonas* are unpublished: The position of *Lemna* chloroplast in the dendrogram of relationship is taken from ref. 8. 1, Sequence present; 0, sequence not present; *, modified nucleotide. Sequence C$_{4-5}$UUACC[6] is listed as CCCCUUACG, because the shorter version is more likely to be the accurate one (C. R. Woese, personal communication). a, For S_{AB} calculation all 3′ termini (except that of *Euglena* chloroplast) are treated as identical[6].

† Listed as AAC, AC, AG by Bonen *et al.*[6].

and the cyanobacteria *Nostoc*, *Fischerella*, *Agmenellum* and *Aphanocapsa* strains are as high (0.42–0.51) as those found for *Nostoc* and *Fischerella* on the one hand and *Aphanocapsa* and *Agmenellum* on the other (0.46–0.50) (*Nostoc* and *Fischerella* exhibit a high S_{AB} value of 0.69). *Synechococcus* strains show less rRNA sequence homology with *Prochloron*, and with the other cyanobacteria (0.34–0.45). Chloroplasts from *Porphyridium*, *Zea* and *Lemna* exhibit similar low S_{AB} values to *Prochloron* (0.31–0.35) (chloroplasts of *Lemna* and *Zea* are themselves highly related: 0.71)[8]. Chloroplasts of *Euglena* and *Chlamydomonas* show even less RNA homology with *Prochloron* (0.26 and 0.23 respectively), having S_{AB} values similar to those found for *Prochloron*, *Escherichia coli* (0.21)[10] and *Bacillus subtilis* (0.24)[18].

The comparative analysis of the 16S ribosomal RNA shows *Prochloron* definitely to be a member of the cyanobacteria–chloroplast line of descent. However, as *Prochloron* does not show the same, low S_{AB} value as all members of this line, it cannot be regarded as a direct and independent descendent of the ancient cell that gave rise to the line. Furthermore, although *Prochloron* resembles the chloroplasts of green algae and plants in respect of pigment composition and the topography of the thylakoids, it is phylogenetically not specifically related to them; this would have resulted in specifically higher S_{AB} values to the chloroplast in question.

The degree of relatedness found between *Prochloron* and the chloroplast of *Lemna* and *Zea* is only remote, while that to the chloroplasts of *Euglena* and *Chlamydomonas* is even more distant (note that the 16S rRNA catalogues of the algal chloroplasts lack some of the universal oligonucleotides found in almost all other members of this cluster; (see Table 1). This may indicate that these chloroplasts have a 'fast clock'[8], resulting in deeper apparent than true branching. A striking example of this is seen in the very low S_{AB} value between the chloroplasts of *Euglena* and *Chlamydomonas* (0.16). The inclusion of the missing oligonucleotides would raise the S_{AB} values of the *Euglena* and *Chlamydomonas* chloroplasts to *Prochloron*, *Nostoc* and relatives (to ~0.30).

The high similarity coefficient between *Prochloron* and the cyanobacteria indicates that, phlogenetically, *Prochloron* is a member of the cyanobacteria. The RNA of *Prochloron* is more similar to that of *Nostoc* and its relatives than to the RNA of *Synechococcus* strains. The deep branching point of *Synechococcus* strain 6301 in the phylogenetic tree is definitely not due to a 'fast clock' of its 16S rRNA (C. R. Woese, personal communication).

Triangle above the diagonal: number of bases in sequences common to each pair of catalogues (for hexamers and larger). Bottom triangle: S_{AB} values for each pair of catalogues. Calculations were done as described in ref. 20; only those oligonucleotides which were comprehensively published previously[6] are used for S_{AB} calculation. Due to the omission of pentamers in the calculation, similarity coefficients for cyanobacteria and chloroplasts are lower than the published ones[6], resulting in lower branching points of the evolutionary lines in the dendrogram of relationship (Fig. 1) compared with those published[6,8].

It is generally believed that chlorophyll *b* is an extraordinarily conserved molecule. If this is the case, *Prochloron* actually is the direct descendent of the common ancestor of the chloroplasts and the cyanobacteria; but it seems that chlorophyll *b* was lost more than once in the chloroplast–cyanobacteria line of descent. An alternative explanation may be that *Prochloron* is an offshoot of the cyanobacteria that 're-invented' chlorophyll *b* and, as a result, could afford to lose its phycobiliproteins. The possibility of a co-occurrence of chlorophylls *a* and *b* in Cyanophyta, together with the resulting taxonomic problems, have already been discussed[19].

Our results do not exclude the possibility that the common ancestor of chloroplasts and cyanobacteria was a *Prochloron*-type organism, but it seems unlikely that the direct ancestor of the *Prochloron* we investigated played this part.

We thank Drs Lanna Cheng and Ralph A. Lewin for help in collecting and identifying *Prochloron*. This work was supported by the Deutsche Forschungsgemeinschaft.

Substrate and sequence specificity of a eukaryotic DNA methylase

Yosef Gruenbaum, Howard Cedar & Aharon Razin

Department of Cellular Biochemistry, The Hebrew University–Hadassah Medical School, Jerusalem, Israel 91010

In eukaryotic DNA, 50–90% of the dinucleotide sequence C-G is methylated. Most methylated sites are apparently placed at fixed locations in the genome and this methylation pattern is faithfully inherited from generation to generation[1]. Holliday and Pugh[2] and Riggs[3] have suggested that methyl moieties are inherited in a semi-conservative fashion during DNA replication, and this model has been confirmed by experiments in which methylated DNA was integrated into mouse L-cells following DNA-mediated gene transfer[4–6]. For this mechanism to operate, two basic requirements must be satisfied: (1) methyl moieties must be symmetrically placed on both strands of the DNA[7,8] and (2) the cellular methylase should be specific for the hemi-methylated substrate present during DNA replication. Here we demonstrate conclusively that the preferred substrate *in vitro* for the mouse ascites DNA methylase is indeed hemi-methylated DNA. Furthermore, this enzyme seems to methylate exclusively cytosine residues located at the dinucleotide C-G.

The lack of a suitable substrate for the eukaryotic methylase has hampered the study of its activity and sequence specificity. Preliminary results have suggested that the preferred substrate for this enzyme may be hemi-methylated DNA[9]. To test this hypothesis we have prepared hemi-methylated ΦX DNA *in vitro* using primed repair synthesis with single-stranded ΦX DNA as template in the presence of the nucleotides dATP, dGTP, dTTP and 5-methyl-dCTP. The product of this reaction is a covalently closed circular duplex ΦX DNA (RFI) in which the complementary strand is methylated at every cytosine residue (all sequences are in the 5′→3′ direction). This hemi-methylated molecule is a very efficient substrate for DNA methylation *in vitro*, having an initial rate of methylation 100-fold greater than that of either single-stranded or double-stranded ΦX DNA molecules (Fig. 1). Using excess enzyme, we determined that the maximum methylation obtainable for hemi-methylated ΦX DNA is 70 pmol methyl per μg DNA, which is consistent with a methylation level of ~100%, assuming that only C-G residues, representing 4.5% of the ΦX dinucleotide content[10], undergo modification.

It has been shown that when hemi-methylated ΦX DNA is inserted into mouse L-cells by DNA-mediated gene transfer, only methylation at C-G residues is inherited from generation to generation[5]. This selectivity is presumably determined by the enzymatic specificity of the cell methylase. This hypothesis was tested by methylating duplex hemi-methylated ΦX DNA by the ascites tumour cell methylase *in vitro* and analysing the sequence specificity of the reaction. Modified nearest-neighbour analysis[11] of *in vitro* methylated ΦX DNA indicated that 95% of the C-G residues were indeed modified. However, this technique is unsuitable for studying specificity because it detects methyl groups on the *in vitro* synthesized fully methylated complementary strand as well as those added onto the viral strand by the ascites methylase *in vitro*. We therefore used the restriction enzyme *Hae*III to develop a method for measuring only those

0028-0836/82/070620—03$01.00

methylations inserted enzymatically. Although *Hae*III will not cleave hemi-methylated ΦX DNA, this enzyme does produce nicks in the unmethylated strand at its restriction site[12]. Thus, when hemi-methylated ΦX DNA is nick-translated using *Hae*III as the nicking agent, labelled nucleotides are incorporated exclusively into the unmethylated strand. Following eukaryotic methylation *in vitro*, the locations of the enzymatically introduced methyl moieties could be determined by nearest-neighbour analysis (Fig. 2)[11]. This experiment showed that the dinucleotide C-G undergoes extensive modification while other cytosine-containing sequences are not recognized to any appreciable degree by this animal cell enzyme. These results do not completely rule out methylation at other sites but indicate that in the reaction conditions used, the major site of methylation is the sequence C-G.

The results presented here show conclusively that hemi-methylated DNA is the preferred substrate for DNA methylation *in vitro* by the animal cell methylase. This property of the enzyme is consistent with the proposed model of methylation inheritance whereby methylation occurs on nascent DNA immediately following DNA synthesis during replication or repair. Assuming specificity for hemi-methylated sites, this mechanism guarantees that the modification will be inherited at previously methylated sites, while unmethylated sites will remain unmethylated. The process requires the presence of symmetrical cytosine residues on both strands of the DNA. In animal cells symmetry is provided by the dinucleotide sequence C-G. Any other cytosine-containing dinucleotide cannot serve as a template for methylation because it would lack a methylatable cytosine residue in the opposite strand. In fact, as shown here, the animal methylase recognizes only the sequence C-G. Note that higher plant DNA is methylated at C-X-G residues as well as the expected C-G sites[13]. This is in keeping with the strand symmetry of cytosine residues required for methylation inheritance. These sites cannot, however, be methylated by the animal cell enzyme either *in vivo*[5] or *in vitro* (present study).

Although >95% of all animal DNA methylation occurs at the sequence C-G[11], several reports have indicated methylation at C-C residues[14–16]. In particular, specific *Msp*I (CCGG) sites located in the 5′-flanking region of the human γ-globin genes are modified at the external cytosine. These unusual methyl moieties also seem to be faithfully inherited by almost all cells during cell differentiation[14,15]. Although this external cytosine of the *Msp*I site does not undergo methylation either *in vivo*[5] or *in vitro* (this study), we cannot rule out the possibility that such methylation can occur in special conditions either by the cell

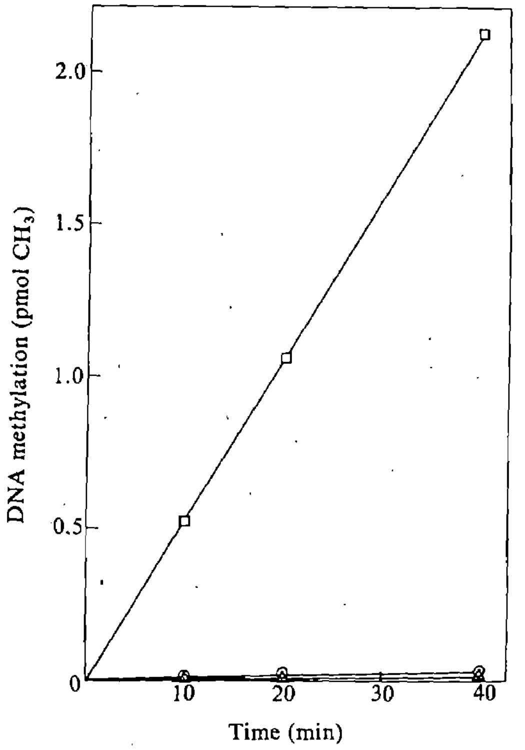

Fig. 1 Substrate specificity of DNA methylase from mouse ascites tumour cells. DNA of the bacteriophage ΦX174: single-stranded, double-stranded (RF) and *in vitro* synthesized hemi-methylated duplex were prepared as previously described[12]. The methylase preparation was a partially purified fraction III from mouse ascites tumour cells[9]. The methylation reaction was carried out at 37 °C in a 25 μl volume containing 0.2 mM dithiothreitol, 10 mM EDTA, 10 mM Tris-HCl (pH 7.9), 30 mM NaCl, 15% (v/v) glycerol, 16 μM *S*[Me-^{3}H]adenosylmethionine (Amersham, 15 Ci mmol^{-1}), 0.07 μg single-stranded or double-stranded phage DNA or 0.14 μg hemi-methylated DNA and enzyme (10 μg protein). The reaction was terminated at various times and DNA purified and analysed for the incorporation of radioactive methyl moieties as described elsewhere[11]. This reaction was found to be linear for at least 2 h. Using higher levels of enzyme, the reaction reached saturation at a level of ~9.5 pmol methyl incorporation. The initial rate of methylation, as calculated from this curve and other experiments, was 3.7 pmol h^{-1} for hemi-methylated DNA (□), 0.05 pmol h^{-1} for single-stranded DNA (○) and 0.03 pmol h^{-1} for double-stranded DNA (△). Note that 0.14 μg hemi-methylated DNA corresponds to 0.07 μg of substrate available for methylation. The rate of reaction using hemi-methylated DNA was also shown to be 100-fold greater than for other DNA substrates in additional experiments using various substrate and enzyme concentrations.

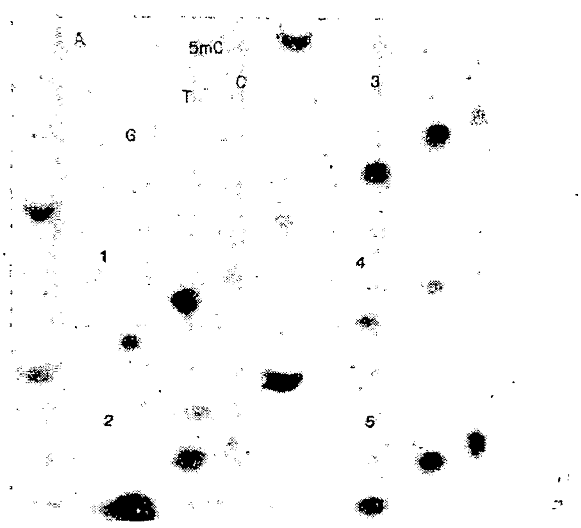

Fig. 2 Sequence specificity of the ascites DNA methylase. Hemi-methylated ΦX174 DNA[12] (0.3 μg) was incubated with 16 U *Hae*III (Biolabs) for 3 h at 37 °C in a 20 μl incubation mixture as recommended by the enzyme manufacturer. The reaction was terminated by incubation for 10 min at 60 °C. This solution of nicked DNA was brought to a volume of 50 μl containing 66 mM Tris-HCl pH 7.4, 6.6 mM MgCl$_2$, 10 mM dithiothreitol, 1 μM of one [α-^{32}P]dNTP (670 Ci mmol^{-1}, NEN) and 50 μM of the other three unlabelled dNTPs and incubated with 30 U *Escherichia coli* DNA polymerase I (Biolabs) to replace ~10% of the unmethylated strand. *In vitro* methylation was carried out on one half of this DNA for 3 h at 37 °C in a volume of 125 μl containing 10 mM EDTA; 16 μM *S*[Me-^{3}H]adenosylmethionine, 0.1 μg nick-translated DNA and 35 μl partially purified ascites DNA methylase (fraction III, 45 μg protein)[11]. The other half of the nick-translated DNA sample served as a non-methylated control. Methylated and non-methylated DNA were digested to deoxynucleoside 3′-monophosphates by micrococcal nuclease and spleen phosphodiesterase and the nucleotides separated by TLC as described previously (bottom to top, 1st dimension; left to right, 2nd dimension)[11]. Autoradiographs of such chromatograms are as follows: (1) DNA before enzymatic methylation, nick-translated with [α-^{32}P]dGTP. (2) DNA after enzymatic methylation, nick-translated with [α-^{32}P]dGTP. (3) DNA after enzymatic methylation, nick-translated with [α-^{32}P]dCTP. (4) DNA after enzymatic methylation, nick-translated with [α-^{32}P]dTTP. (5) DNA after enzymatic methylation, nick-translated with [α-^{32}P]dATP. Following autoradiography the spots were scraped and the amount of radioactivity in each spot was determined by scintillation counting. In this experiment, when DNA, after enzymatic methylation, was labelled with [α-^{32}P]dGTP, 60% of the cytosine was found to be methylated. When DNA was labelled with other radioactive nucleotides, less than 0.5% of the cytosine was in 5mC. The ratio of counts for all the nucleotides on each TLC plate was found to be consistent with the nearest-neighbour frequencies of the ΦX viral strand[10]. In frame 2 the spot corresponding to dGMP is seen to be stronger than expected from the nearest-neighbour frequencies. This was seen only in the *in vitro* methylated sample labelled with [α-^{32}P]dGTP and seems to be an artefact of the preparation and purification of the DNA following methylation, as the ratios of intensities of the other spots on this chromatogram are appropriate. Abbreviations used: A, dAMP; C, dCMP; T, dTMP; 5mC, 5methyl-dCMP.

maintenance enzyme itself or by some other enzymatic activity *in vivo*.

Whereas most somatic cellular methylation is carried out by a maintenance enzyme recognizing hemi-methylated DNA, *de novo* methylation has occasionally been observed in virus-transformed cells[17,18]. Although the enzyme examined here carried out inefficient *de novo* methylation on double-stranded or single-stranded DNA, this same enzyme may operate *in vivo* in special conditions to produce new methylated sites. Recent studies have shown that specific genes may be undermethylated in certain somatic cells as compared with germ-line DNA[19,20]. This change presumably occurs during differentiation by a process of demethylation achieved by DNA replication in the absence of concomitant methylation[1]. Thus, the control of the cellular DNA methylase may be an important factor in the regulation of gene activity.

Long terminal repeats of endogenous mouse mammary tumour virus contain a long open reading frame which extends into adjacent sequences

The integrated DNA copies (proviruses) of RNA tumour virus genomes are flanked by long terminal repeat (LTR) sequences, which are generated by the duplication of segments present at both ends of the viral RNA[1]. LTRs vary in length from 330 (ref. 2) to 1,328 (this paper) base pairs (bp). The primary viral transcript starts in the left LTR (L-LTR) and terminates in the right LTR (R-LTR)[3]. We have now sequenced both LTRs from an inherited (endogenous) mouse mammary tumour virus (MMTV) of the GR strain. This provirus, which is one of five present in the haploid genome of GR mice[4], does not produce virus[5] and is not identical with the exogenous MMTV of GR mice[6]. The provirus (GR40) could nevertheless be transcribed and its transcription hormonally regulated after cloning and transfection into mouse L cells[7]. The LTRs are identical and exhibit the following features: a terminal inverted 6-bp repeat, a Goldberg–Hogness (TATAAA) sequence, sequences which have been implicated in polyadenylation and the termination of transcription, and an open reading frame. The open reading frame of the R-LTR starts at the *env*/LTR junction and encodes a 36,700-molecular weight (M_r) protein. The open reading frame of the L-LTR extends into the adjacent mouse sequence. A host sequence of 6 bp at the site of integration into the mouse chromosome is directly repeated.

The MMTV proviral fragment in λ clone GR40 is shown schematically in Fig. 1*a*. To sequence the LTRs we adopted the strategy described in ref. 8 (Fig. 1*b–e*). DNA subfragments were cloned into pBR322 and a series of staggered deletions made. All the deletions extended from a unique restriction enzyme site in pBR322. Sequencing from this site resulted in an overlapping series of sequences which could then be used to reconstitute that of the subcloned fragment. The sequence extending from the *Pst*I site at the 5′ end of the L-LTR and into the adjacent mouse region was obtained in two ways. A *Pst*I restriction fragment covering the left junction was end-labelled and sequenced by the base modification method[9]. To confirm the sequence across the *Pst*I site we subcloned *Hae*III and *Alu*I fragments into the single-strand bacteriophage M13mp7 (ref. 10) and subjected appropriate clones to the chain termination sequencing method[11].

The LTRs at the ends of the GR40 provirus have the same sequence (shown as a single line numbered 1–1328 in Fig. 2). The following findings suggest that positions 1 and 1,328 represent the limits of the proviral LTR. (1) The flanking sequences of both LTRs diverge beyond these points. (2) Six nucleotides at the ends of the repeated sequence form an inverted repeat (underlined at positions 1–6 and 1,323–1,328 in Fig. 2). The inverted repeats are the same as those found at the termini of other MMTV LTR junctions sequenced[12,13]. Inverted terminal repeats 3–23 bp long are common to all retroviruses[14], insertion sequences (IS elements) and most transposons[15]. In the latter cases they are required for integration[16]. (3) Six nucleotides in the host DNA adjacent to the LTRs are directly repeated (underlined at positions −6 to −1 and 1,329 to 1,334 in mouse flanking sequences). Such direct repeats are also a common feature among LTRs, IS elements and transposons[15], and apparently result from the duplication of a 3–6 bp host sequence during integration[17–19]. Integration is also thought to be accompanied by the loss of 2 bp from both ends of the linear DNA intermediate[12,13,19]. In GR40 they can be tentatively identified by reference to the internal LTR junctions. The 2 bp lost from the 5′ end of the linear DNA would correspond with the A-A at positions −1 and −2 of the R-LTR. Similarly the 2 bp lost from the 3′ end would correspond with the G-C at positions 1,329–1,330 of the L-LTR. (4) The proviral DNA sequence left of the R-LTR at positions −1 to −9 (dotted in Fig. 2) is identical to the corresponding sequence in avian sarcoma virus and thought to be part of the site involved in the initiation of plus-strand DNA[20]. (5) The primer for minus-strand DNA[21] is $tRNA_3^{Lys}$. A 16 bp sequence in the proviral DNA right of the L-LTR (positions 1,331–1,345, dotted in Fig. 2) matches the 3′-terminal end of the primer.

The identical nature of the LTRs of GR40 was not necessarily expected. As the endogenous provirus is genetically transmitted and silent, there is probably no selection against sequence alterations. The identity of the GR40 LTRs, and their ability to direct specific and hormonally regulated transcription[7], imply that its entry into the germ line was a recent event in evolutionary terms. In contrast, there is a large difference between the endogenous sequence presented here and that of an exogenous LTR from the C3H mouse[13], there being 93 base changes between the two. This suggests that the endogenous GR40 provirus and the exogenous virus of the C3H mouse have evolved separately[22,23].

Several sequences thought to be transcriptional control signals are present in the LTRs. A Goldberg–Hogness

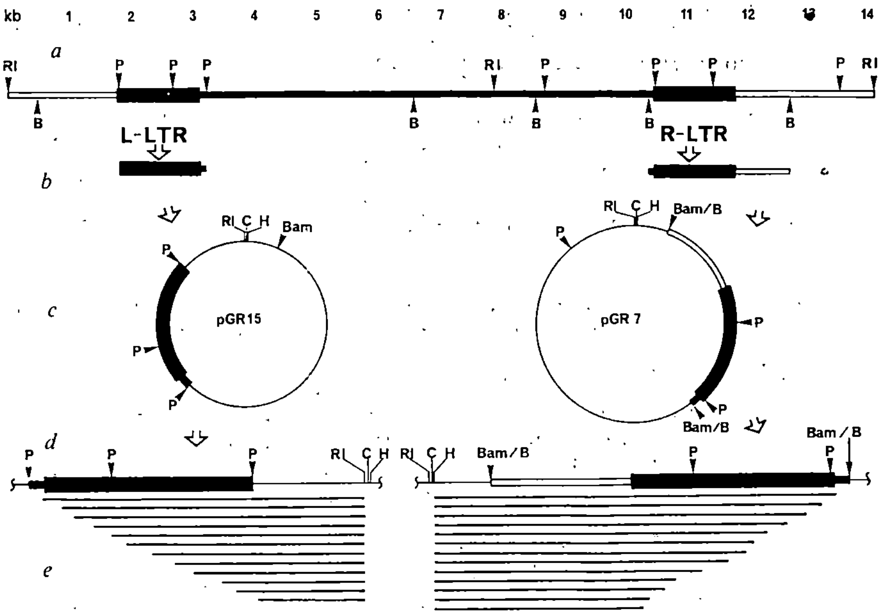

Fig. 1 *a*, Restriction map of the insert in recombinant λ phage Charon 4a/GR40[1]. The solid black region represents the provirus with the LTRs shown thicker; the rest is mouse flanking DNA. Restriction endonuclease sites: Bam, *Bam*HI; B, *Bgl*II; C, *Cla*I; H, *Hin*dIII; P, *Pst*I; RI, *Eco*RI. The two *Eco*RI fragments of the insert were subcloned into pBR322 (not shown). *b*, A 1.4 kb *Pst*I fragment contains all but 11 bp of the L-LTR, and a 2.2 kb *Bgl*II fragment contains all of the R-LTR. *c*, These fragments were introduced into the *Pst*I and *Bam*HI sites respectively of pBR322, in the orientations shown. From the two resulting plasmids, pGR15 and pGR7, two sets of deletions were produced using the method described elsewhere[8]. Briefly, *Eco*RI linkers were ligated onto pGR15 molecules which had been randomly linearized by treatment with DNase I. Digestion with *Eco*RI and size fractionation on a low-gelling temperature agarose gel were followed by re-ligation and the transformation of Ca^{2+}-treated *Escherichia coli* cells. Deletions in pGR7 were created in an analogous way, but using *Hin*dIII linkers. *d*, The LTR regions of the two plasmids are shown relative to the *Eco*RI, *Cla*I and *Hin*dIII sites of pBR322. *e*, The deleted DNA is represented by lines which correspond in size and position to the map in *d*. Each member of a set differs in length by ~100 bp from the next. Sequencing by the method of Maxam and Gilbert[9] into the LTR from each deletion endpoint produced an overlapping series from which the sequence of the whole LTR could then be reconstituted. *Hin*dIII digestion of pGR7 followed by 5′ end-labelling with [γ-^{32}P]ATP and T4 polynucleotide kinase produces linear molecules labelled at both ends. Subsequent digestion with *Cla*I cleaves off a 5 bp pBR322 terminal fragment and the mixture of fragments may be sequenced directly with no further separation necessary. In the case of pGR15, a terminal 26 bp fragment may be similarly removed by *Cla*I from end-labelled *Eco*RI-digested molecules. As the two sets of deletions enter the LTRs from opposite ends, opposite strands of the LTR are sequenced. The 11 bp missing from the 5′ end of the L-LTR were determined by sequencing from the *Pst*I site at map position 1.8 in *a*. The sequence across the *Pst*I site was confirmed by chain termination sequencing[11] using fragments cloned into the single-stranded DNA bacteriophage M13mp7 (ref. 10).

Fig. 2 The identical nucleotide sequences of the GR40 LTRs are written as a single line numbered 1–1,328. L-LTR flanking regions are presented above those of the R-LTR. Sequences left of the LTRs are numbered negatively. Amino acid sequences generated by the open reading frames are given in the single-letter code. The orf sequence, and its alternative N-terminal peptide, are written above the corresponding nucleotides. The translation of the reading frame in the opposite strand is shown below the appropriate DNA sequence. Stop codons flanking open reading frames are indicated by arrow heads pointing in the direction in which they are to be read. Underlined sequences are referred to in the text. U3, R and U5 represent the unique 3′ terminally repeated and unique 5′ sequences of MMTV genomic RNA respectively; the corresponding proviral regions are delimited by vertical lines. The R sequence is defined at its left and right ends by the positions at which transcription starts and stops. Nucleotides associated with the initiation of synthesis of the plus and minus DNA strands are marked by dots.

(TATAAA) sequence[24] is present at positions 1,164–1,169. The MMTV mRNA cap site is probably at position 1,196 (ref. 10 and our unpublished S_1 mapping data). Direct sequencing of the viral RNA[25] shows that its 3′ end corresponds with position 1,206. The sequence AGTAAA, an analogue of the sequence AATAAA which may be a signal for polyadenylation[26], is present (underlined at positions 1,187–1,192) 17 bp upstream from this site. Another sequence associated with transcription termination, TTTG[27], is present (underlined at positions 1,225–1,228) 20 bp downstream from the 3′ end of the viral RNA, and flanked by alternating T and G residues.

The LTR sequence possesses an open reading frame, in the direction of viral transcription, with coding potential for a basic 36,700-M_r protein. A similar open reading frame has been found in the exogenous MMTV LTR of the GR mouse (N. Fasel, K. Pearson, E. Buetti and H. Diggelmann, personal communication), and in the exogenous and endogenous MMTV LTRs of the C3H mouse[28]. Dickson and co-workers[29,30] have described the synthesis *in vitro* of a 36,000-M_r protein (orf) from templates containing LTR sequences. In addition, an open reading frame for a 6,600-M_r protein exists in the opposite strand, extending from position 160 to −20 in the MMTV *env* region, to −14 in the mouse flanking sequence, or, when read from the circular DNA intermediate, to 1,316 in the R-LTR.

An interesting feature of the *orf* open reading frame is that the first AUG codon is composed of an A, which is the last nucleotide of the *env* region, and a T-G representing the first two nucleotides of the R-LTR. At the 5′ end of the provirus, integration has replaced the A with a C in the AUG codon, thereby creating a CUG (lysine) codon. Another start codon, in phase with the open reading frame, occurs by chance in the mouse DNA at positions −11 to −13. Note that in both cases the open reading frame is preceded by a stop codon in phase. Furthermore the open reading frame is contained within the unique 3′ sequence of the genomic RNA, and ends at position 959, well before the 3′ end of the RNA at position 1,206.

The corresponding RNAs for these hypothetical proteins have not yet been found. Rightward transcription of the integrated L-LTR would have to start in the flanking mouse sequence. Transcription of the R-LTR might start from an internal promoter or from the L-LTR. A further possibility is that *orf* mRNA is transcribed from the L-LTR in circular DNA intermediates containing two copies of the LTR in tandem[31]. In this configuration the GC which we suppose to be present at the 3′ end of the linear DNA intermediate would be juxtaposed with the A-A at its 5′ end[13], resulting in the AUG codon at the beginning of the L-LTR being retained and its *orf* coding region brought under the influence of the R-LTR promoter. No AUG codons intervene between the R-LTR Goldberg–Hogness (TATAAA) sequence and the appended L-LTR *orf* coding sequence. Transcription in this case would generate an *orf* mRNA of unit LTR length.

The extra length of the LTR of MMTV as compared with other retroviruses can be accounted for by the open reading frame. Whether this difference is associated with another special feature of MMTV—its hormonally mediated transcription—may be answered by testing after transfection[7] the biological properties of the deletion mutants described here.

We thank R. Staden for computer programs used in DNA sequence analysis.

Expression of human *hprt* gene on the inactive X chromosome after DNA-mediated gene transfer

A.J.R. de Jonge*, P. J. Abrahams†, A. Westerveld* & D. Bootsma*

* Department of Cell Biology and Genetics, Erasmus University, Rotterdam, The Netherlands
† Laboratory of Physiological Chemistry, Sylvius Laboratory, Leiden, The Netherlands

The paternal or maternal mammalian X chromosome is inactivated ('lyonization') at random early in the development of the female embryo[1,2]. Once established, the inactivation of the chromosome is maintained in the cell and in all its descendants. However, spontaneous local reactivation of the inactive X chromosome is found at low frequency in human–mouse hybrid cells[3,4]. So far only the X_g locus[5,6] and the locus for microsomal steroid sulphatase (*sts*)[7] (both assigned to the short arm of the X chromosome), have been shown to escape inactivation. The locus for hypoxanthine phosphoribosyltransferase (*hprt*) is susceptible to inactivation[8] and humans heterozygous for HPRT deficiency (the Lesch–Nyhan syndrome, L–N)[9], show a mosaic pattern of HPRT activity in their cultured fibroblasts[8]. To investigate the molecular basis of X inactivation, we have used DNA isolated from each of the two subpopulations of a L–N heterozygote, to transform cultured HPRT-deficient mouse fibroblasts. Transformation of the mouse cells with the inactivated human *hprt*$^+$ gene occurred with essentially the same efficiency as with the active human *hprt*$^+$ gene. Thus, reactivation of the lyonized human *hprt* locus is possible after interspecific DNA-mediated gene transfer.

To obtain sufficient cells of only the HPRT$^+$ or only the HPRT$^-$ subpopulation, primary fibroblasts of the L–N heterozygote (cell strain 79RD19) were transformed using the *ori*$^-$ simian virus 40 (SV40) mutant originally isolated by Gluzman *et al.*[10] and various of these transformed clones were tested for HPRT expression. One HPRT$^-$ clone, SV1 (the inactivated X chromosome carries the *hprt*$^+$ allele) and one HPRT$^+$ clone, SV3 (the active X chromosome carries the *hprt*$^+$ allele) were expanded for DNA isolation. Immediately before collection, the cells were checked again for HPRT$^+$ or HPRT$^-$ phenotype by measuring ^{3}H-hypoxanthine incorporation and also by a growth test in two selective media. Cells (10^7) of each clonal cell line were plated in medium selecting either for (hypoxanthine–aminopterin–thymidine (HAT) medium[11]) or against (medium containing 6 μg ml^{-1} 6-thioguanine, 6-TG) the expression of HPRT in the cells. Cells having a phenotype which differed from that expected were not observed in either test.

Table 1 Transformation of LTH1 and LTK⁻ with HeLa, SV1 and SV3 DNA

	LTH1 Selection for HPRT⁺			LTK⁻ Selection for TK⁺		
DNA donor	Plates with clones/total plates	No. of clones	Transfer frequency	Plates with clones/total plates	No. of clones	Transfer frequency
No DNA	0/25	0	0	0/7	0	0
HeLa	5/15	7	0.2×10^{-6}	4/4	18	2×10^{-6}
SV1	6/10	11	0.5×10^{-6}	3/3	26	4.5×10^{-6}
SV3	9/10	21	1×10^{-6}	3/3	17	3×10^{-6}

DNA was isolated using a modification of a previously described method[26]. DNA–calcium phosphate precipitate was produced by slowly adding DNA, dissolved at 40 μg ml^{-1} in 10 mM Tris-HCl *p*H 7.6, 1 mM EDTA, 250 mM $CaCl_2$ to an equal volume of HEBS buffer[27], with agitation. After 30–45 min, 1 ml of the fine precipitate was added to the medium over 2×10^6 cells in a 10-cm cell culture dish. Control dishes received calcium phosphate precipitate without DNA. Post-treatment with 10% dimethyl sulphoxide[28] was given 3.5–4 h after addition of precipitate. Selective medium (LTH1, HAS medium[13]; LTK⁻, HAT medium[11]) was added 24 h later and changed initially every second or third day, later every fifth to seventh day. Clones appeared after 2–4 weeks and were isolated using glass cloning cylinders. The plates were then fixed and stained to detect other clones. The medium used in all cell culture procedures was a 1 : 1 mixture of Ham's F10 and Dulbecco's minimal essential medium (MEM; Flow) containing 5% fetal and 5% newborn calf serum and antibiotics, gassed with 5% CO_2.

Furthermore, the presence of an inactive X chromosome was verified in these cell lines by staining the Barr body in interphase nuclei (Fig. 1).

DNA isolated from SV1 or SV3 was used to transform mouse LTH1 cells. LTH1 is an HPRT-deficient subline of LTK⁻ (ref. 12), which we have isolated after selection for a spontaneous mutant by culturing in 6-TG medium. Reversion of LTH1 to an HPRT⁺ phenotype was $<2\times10^{-8}$ when tested by culturing cells in medium containing hypoxanthine as the exogenous purine source and azaserine to block the *de novo* biosynthesis of purines (HAS medium[13]). We have tested HPRT-deficient cell lines of different origins in transformation experiments with human HeLa DNA and found the highest transformation frequency of the HPRT⁺ phenotype using LTH1 cells as DNA recipients (our unpublished results). The results of DNA-mediated gene transfer of the *hprt* locus into LTH1 cells are shown in Table 1. For comparison, we also selected for transfer of the thymidine kinase (*tk*) locus into LTK⁻ cells using the same DNA–calcium phosphate precipitates.

The *hprt* gene was transformed by SV1 DNA at a frequency intermediate between those obtained using HeLa and SV3 DNA. In addition, the transformation frequency of the *tk* locus in SV1 DNA was not significantly different from the frequencies obtained with the other DNAs used although for each DNA, transfer of the *hprt* locus into LTH1 cells occurred at a lower frequency than transfer of the *tk* locus into LTK⁻ cells. Evidently there were no significant differences in transformation capacity between the different DNA preparations for either the *tk* or *hprt* locus. From LTH1 cells treated with HeLa, SV1 and SV3 DNA, respectively, 2, 9 and 15 transformed clones were isolated.

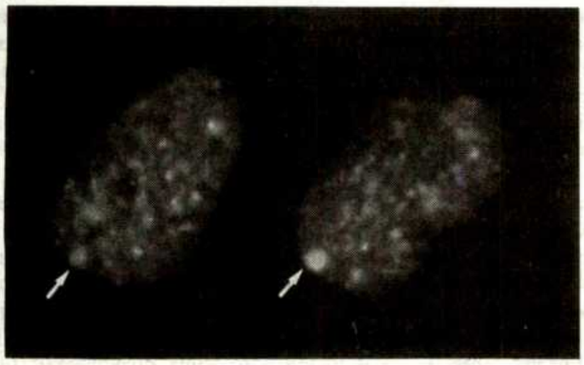

Fig. 1 Barr body in SV1 cells. After fixation in methanol/acetic acid (3 : 1) the cells, grown on coverslips, were air-dried and stained for 10 min in a 0.5% atebrin solution in methanol. After rinsing and mounting in 0.07 M phosphate buffer *p*H 6.5, the cells were examined by fluorescence microscopy and photographed. The Barr body is indicated by an arrow.

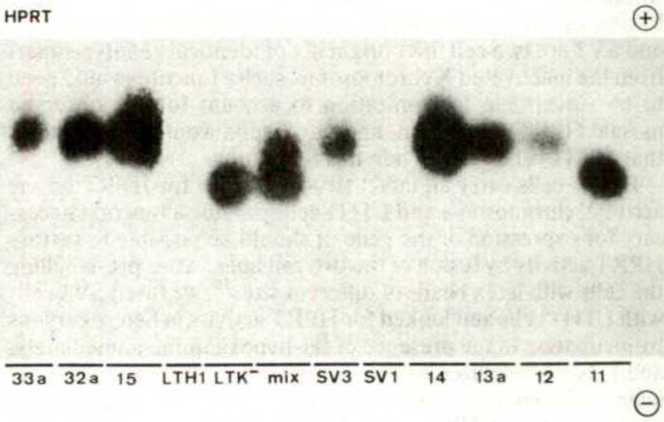

Fig. 2 Cellogel electrophoresis of HPRT. Cell lysates were produced by sonication and electrophoresis was carried out according to Meera Khan[14]. Enzyme activity was visualized by incubation with ^{14}C-hypoxanthine and autoradiography[15]. For an explanation of SV1, SV3, LTH1 and LTK⁻, see text. Clones 12, 13a, 14 and 15 are independent transformant clones isolated after treatment of LTH1 cells with SV1 DNA. Clone 11 appears to be a revertant. Clones 32a and 33a are independent clones isolated after treatment of LTH1 cells with SV3 DNA. Mix is an artificial mixture of extract from LTK⁻ and SV3 cells.

In a number of independent transformed cell lines isolated from different culture dishes, we identified the HPRT and glucose-6-phosphate dehydrogenase (G-6-PD) activities by electrophoresis on Cellogel[14,15] (Table 2). Figure 2 shows the electrophoretic mobility of human (SV3) and murine (LTK⁻) HPRT. In extracts of SV1 and LTH1 cells, HPRT was not detectable, while in transformants isolated from LTH1 cells treated with SV1 DNA, human HPRT was synthesized. One cell line (clone 11) showed HPRT of murine electrophoretic mobility and was assumed to be a revertant. In all the transformants tested, only the murine G-6-PD was present.

The results are most readily explained by a reactivation of the lyonized *hprt* locus after interspecific DNA transformation. A simple reversion of the *hprt* mutation on the active X chromosome in the donor strain SV1 appears unlikely because of the equal transformation frequencies obtained with DNA isolated from SV1 and SV3, and from results of the tests performed on the cells immediately before DNA isolation. An alternative explanation is that in the cells of the particular L–N heterozygote used, the HPRT deficiency was not due to a mutation in the structural gene for HPRT, but due to a defect in some other function necessary for expression of the gene. This

Table 2 Identification of HPRT and G-6-PD activities in cell lysates of independent transformant clones

DNA donor	Transformant	Electrophoretic mobility of HPRT	G-6-PD
HeLa	95.1-1	H	M
	95.1-2	H	M
SV1	96.1-11	M	M
	96.1-12	H	M
	96.1-13a	H	M
	96.1-14	H	M
	96.1-15	H	M
SV3	96.1-31a	H	M
	96.1-32a	H	M
	96.1-33a	H	M
	96.1-34	H	M
	96.1-36	H	M

H represents human, M murine electrophoretic mobility.

would render the SV1 cells phenotypically HPRT$^-$ despite their having an intact *hprt* gene on the active X chromosome. As SV1 and SV3 are two cell lines originally of identical genotype apart from the inactivated X chromosome, such a function would need to be susceptible to lyonization to account for the observed mosaic HPRT expression, and our results would then indicate that LTH1 cells can provide this function.

If SV1 cells carry an intact structural gene for HPRT on the active X chromosome and LTH1 cells provide a function necessary for expression of the gene, it should be possible to restore HPRT activity by fusion of the two cell lines. After pre-labelling the cells with latex beads of different sizes[16], we fused SV1 cells with LTH1 cells and looked for HPRT activity in heterokaryons by incubation in the presence of ^{3}H-hypoxanthine immediately, and 1,2 or 3 days after fusion. At each time point we examined at least 1,000 heterokaryons having 2–10 nuclei per cell, but found no restoration of HPRT activity. It is thus highly unlikely that SV1 cells have an active X chromosome carrying an intact structural gene for HPRT which can become expressed in LTH1 cells as a result of some murine function. These results agree with data reported elsewhere[17,18] which suggest that in cells obtained from L–N patients, the mutation has affected the structural gene for HPRT.

Several mechanisms proposed for X inactivation agree with our results. (1) Taking the human X chromosome to be 2×10^5 kilobase pairs (kbp) (1/23 of the haploid genome) and the average length of the isolated DNA molecules to be 100 kbp (estimated by agarose gel electrophoresis), one isolated DNA molecule could represent, on average, only 0.05% of the X chromosome. If there are one or a few 'inactivation centres'[19] from which inactivation of the X chromosome is maintained, our procedure could have caused an uncoupling of such a centre from the *hprt* locus, resulting in expression of the gene. (2) Recently, evidence has been obtained that DNA methylation could be involved in X-chromosome inactivation[20]. Also, almost total, random methylation of a DNA sequence inhibits the expression of that sequence after DNA transformation[21]. We have shown here that the *hprt* locus, kept inactive in human cells, can be efficiently expressed in rodent cells. Taken together, these findings indicate that the inactive state of the X chromosome is maintained by a species-specific methylation pattern, the human pattern not being recognized as a lyonization signal in the rodent cells. In this respect, it is interesting that Liskay and Evans[22] have not found reactivation in experiments similar to ours, but they performed transfers between rodent cells only. (3) As purified DNA was used in our experiments it is possible that the inactivated state is maintained by non-DNA components of the X chromosome[23].

Our results do not support models based on differences in DNA base sequence being responsible for lyonization[24,25].

The system using the two L–N heterozygote subpopulations as a source of active and inactive X-chromosomal material should enable us to investigate further the possibilities of X-chromosome reactivation, for example after chromosome-mediated gene transfer, or in intraspecific transfer experiments.

Inter-replicon transposition of Tn*1*/*3* occurs in two sequential genetically separable steps

Paul A. Kitts, Angus Lamond & David J. Sherratt

Department of Genetics, University of Glasgow,
Glasgow G11 5JS, UK

The 4,957-base pair (bp) transposon Tn*3* encodes three polypeptides, two of which are needed for normal inter-replicon transposition and one, β-lactamase, which is responsible for the transposon's ampicillin resistance (Ap^r)[1,2]. The closely related transposon Tn*1* specifies three interchangeable polypeptides of identical function. The 1,015-amino acid *tnp*A protein is essential for transposition, whereas the 185-residue *tnp*R protein regulates the rate of transposition[3,4] and is required for the generation of normal end products of inter-replicon transposition[5,6]. Here we report the inter-replicon transposition properties of *tnp*A$^-$ *tnp*R$^-$ derivatives of both Tn*1* and Tn*3*. We show that the *tnp*A product is sufficient to generate a transpositional co-integrate intermediate in which the donor and recipient replicons become fused between two directly repeated copies of the transposon. In the absence or presence of *tnp*A product, such co-integrates are efficiently converted to normal transposition end products in the presence of *tnp*R protein. Two amber mutants selected because of their derepressed *tnp*R-mediated control of transposition are also unable to resolve co-integrate intermediates in a Sup^0 (suppressor minus) background. For each mutant, both mutant phenotypes are suppressed by *Sup*D and *Sup*E but not by *Sup*F, confirming that the *tnp*R coding sequence specifies a single protein having both functions.

0028–0836/82/070626—03$01.00

To test whether *tnp*A and *tnp*R products act independently, we constructed *tnp*A$^-$ *tnp*R$^-$ derivatives of both Tn*1* and Tn*3* (Tn*1031* and Tn*3651* respectively). The structures of the parental plasmids and their deleted derivatives are indicated in Fig. 1. Note that both *tnp*A$^-$ *tnp*R$^-$ derivatives retain the transposon ends and the internal site (*res*) at which *tnp*R-mediated site-specific recombination occurs during resolution of transpositional co-integrates[5,7]. Therefore provision of both *tnp*A and *tnp*R proteins in *trans* by complementation should allow normal transposition of these transposons. Similarly, provision of these gene products separately should allow their individual roles in transposition to be determined.

Our inter-replicon transposition assay depends on the fact that the multicopy plasmids pMB9 (tetracycline resistant, Tc^{r})[8] and pACYC184 (Tc^{r} and chloramphenicol resistant, Cm^{r})[9] are not mobilized during conjugation promoted by the *Inc*W conjugative plasmid R388 (trimethoprim resistant; Tp^{r})[10]. Transposition from transposon-containing derivatives of pMB9 and pACYC184 into non-essential regions of R388 can be simply assayed by crossing out the R388 plasmids and assaying the fraction that contains the transposon. Table 1 summarizes the data from such experiments. *tnp*A$^-$ derivatives of either Tn*1* or Tn*3* fail to complement transposition of the *tnp*A$^-$ *tnp*R$^-$ transposons. In the absence of *tnp*R protein, provision of either Tn*1* or Tn*3* *tnp*A protein results in a high frequency of transposition and a similar high frequency of co-integrate formation. When individual R388::Tn*3651* transconjugant clones were examined, 98% were found to contain the donor plasmid marker. Thus *tnp*A protein results in the generation of stable co-integrates as the sole transposition product (Fig. 1*C*). The structures of these co-integrates were confirmed by both restriction enzyme digestion (Fig. 2) and their resolution patterns (Fig. 3), and are in agreement with the co-integrate structures reported previously[5,11]. In the presence of both *tnp*A

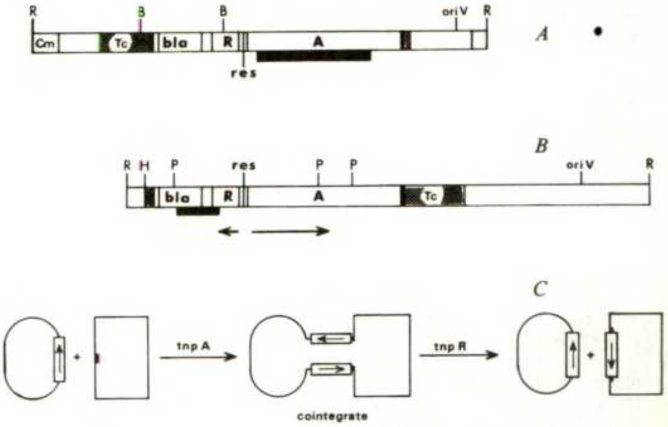

Fig. 1 Construction of *tnp*A$^-$ *tnp*R$^-$ derivatives of Tn*1* and Tn*3*. *A*, Map of pACYC184::Tn*3* and its deleted derivative pACYC184::Tn*365*. The deletion in *tnp*A is indicated by a thick black bar. pACYC184::Tn*3651* (*tnp*A$^-$ *tnp*R$^-$) was constructed by inserting a 1,150-bp *Bgl*II fragment from plasmid F (a gift from Dr R. Thompson) into the *Bam*HI site of the *tnp*R gene. *B*, Map of pMB9::Tn*1* and its deleted derivative pMB9::Tn*103*. The deletion in *tnp*R and the β-lactamase gene (*bla*) is indicated by a thick black bar. A Tn*1* *tnp*A$^-$ *tnp*R$^-$ derivative (pMB9::Tn*1031*) was constructed from pMB9::Tn*103* by deleting the *Pst*I fragment within the *tnp*A gene. In this plasmid, expression of Tc^{r} is under *tnp*R gene control and is coordinately expressed with *tnp*A protein; that is, this plasmid confers Tc^{r} in a *tnp*R$^-$ cell but Tc^{s} in a *tnp*R$^+$ cell. R, *Eco*RI site; B, *Bam*HI site; H, *Hin*dIII site; P, *Pst*I site. oriV indicates origin of plasmid replication. Thick vertical bars indicate transposon boundaries; res (resolution site) indicates the site of action of *tnp*R. Divergent transcription from the *res* region is indicated in Fig. 1*B*. *C*, transposition pathway of Tn*1/3*. Circle, donor replicon; rectangle, recipient replicon; ⇥, transposon.

Track *i*, λCI*857Sam*7 DNA digested with *Hin*dIII. R388::Tn*3651* was derived from the R388::Tn*3651*::pACYC184 co-integrate by recombination across the two copies of Tn*3651*. It has a single copy of Tn*3651* and no pACYC184 sequences. Digestion with *Bam*HI produces the novel B'_1 fragment. ■, Tn*3651* sequences; □, pACYC184 sequences; □, R388 sequences; ▮, *Bam*HI site; ▮, *Pst*I site.

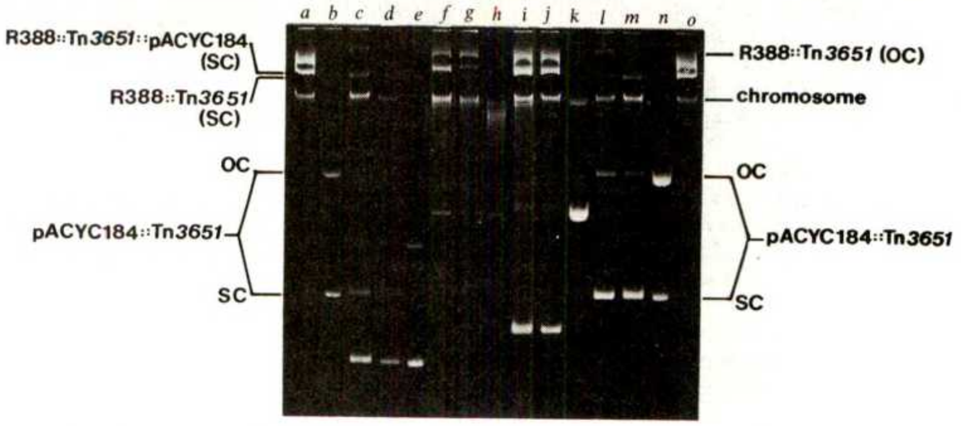

Fig. 3 Resolution of a co-integrate between pACYC184::Tn*3651* and R388, formed by transposition in a *tnp*A$^+$ *tnp*R$^-$ cell. Lanes *a*, *o*, R388::Tn*3651*::pACYC184 co-integrate-containing strain; *b*, pACYC184::Tn*3651* plasmid DNA; *c*, *d*, co-integrate strain + *tnp*A$^-$ *tnp*R$^+$ derivative of pMB8::Tn*3*; *e*, pMB8::Tn*3* *tnp*A$^-$ *tnp*R$^+$ plasmid DNA; *f*, *g*, co-integrate strain + *tnp*A$^+$ *tnp*R$^-$ derivative of ColE1::Tn*3*; *h*, ColE1::Tn*3* *tnp*A$^+$ *tnp*R$^-$ plasmid DNA; *i*, *j*, co-integrate strain + *tnp*A$^-$ *tnp*R$^-$ derivative of pMB8::Tn*3*; *k*, pMB8::Tn*3*; *tnp*A$^-$ *tnp*R$^-$ plasmid DNA; *l*, and *m*, co-integrate strain − *tnp*A$^+$ *tnp*R$^+$ pMB8::Tn*3*; *n*, pMB8::Tn*3* plasmid DNA. The plasmid DNA content of cells derived from a single colony was analysed by electrophoresis through 0.8% agarose gels. Cells were lysed by resuspension in electrophoresis buffer containing 2% Ficoll and 1% SDS. After centrifugation (18,000*g* for 15 min) to remove chromosomal DNA and cell debris, the supernatants were loaded directly on to gels. Open circle (OC) and supercoil (SC) bands of the co-integrate and of the resolution products, pACYC184::Tn*3651* and R388::Tn*3651*, are indicated. Note that in tracks *a*, *f*, *g*, *i*, *j* and *o*, the R388 co-integrate copy number is higher than in the tracks containing R388::Tn*3651*. This is because co-integrate replication occurs from the multicopy origin of pACYC184. In tracks *l* and *m*, pACYC184::Tn*3651* and pMB8::Tn*3* co-migrate. The presence and identity of all Tn*3651* derivatives were confirmed after DNA transformation or conjugation.

and *tnp*R proteins, transposition frequencies are generally some 10 times lower than in *tnp*A$^+$ *tnp*R$^-$ cells, with co-integrates occurring between 10^2 and 10^4 times less frequently. In these cases the major transposition end product is a simple transposon insertion into the recipient replicon (Fig. 1*C*), demonstrating that the *tnp*R gene product is involved in conversion of co-integrates to normal transposition end products. That the *tnp*R protein alone is sufficient to mediate this resolution was demonstrated by introducing complementing transposon derivatives into cells carrying *tnp*A$^-$ *tnp*R$^-$ co-integrates (Fig. 3). Providing *tnp*R protein alone (Fig. 3*c*,*d*) or in the presence of *tnp*A protein (Fig. 3*l*,*m*) brings about a rapid resolution of the co-integrates into the normal end products of transposition (Fig. 1*C*). However, the co-integrates are stable in the presence of *tnp*A protein alone (Fig. 3*f*,*g*). Both Tn*1* and Tn*3* *tnp*R gene products act efficiently to resolve co-integrates formed by the Tn*1* *tnp*A$^-$ *tnp*R$^-$ derivative (data not shown). Thus Tn*1* and Tn*3* gene products are completely interchangeable in the two steps of transposition.

Table 1 Complemented transposition of *tnp*A$^-$ *tnp*R$^-$ derivatives of Tn*1* and Tn*3*

Donor transposon type (*tnp*A$^-$ *tnp*R$^-$)	Complementing transposon	Frequency of transposition*	Frequency of stable co-integrate formation†
Tn*3*	—	$<1\times10^{-7}$	$<1\times10^{-7}$
Tn*3*	A$^-$R$^-$ Tn*3*	$<2\times10^{-7}$	$<2\times10^{-7}$
Tn*3*	A$^-$R$^+$ Tn*3*	8×10^{-7}	$<2\times10^{-7}$
Tn*3*	A$^+$R$^-$ Tn*3*	1.6×10^{-2}	1.5×10^{-2}
Tn*3*	A$^+$R$^+$ Tn*3*	3.5×10^{-3}	4×10^{-5}
Tn*3*	—	$<2\times10^{-7}$	$<2\times10^{-7}$
Tn*3*	A$^-$R$^+$ Tn*1*	$<1\times10^{-7}$	$<1\times10^{-7}$
Tn*3*	A$^+$R$^-$ Tn*1*	6.6×10^{-3}	7.3×10^{-3}
Tn*1*	—	ND	$<1\times10^{-6}$
Tn*1*	A$^-$R$^+$ Tn*1*	ND	$<1\times10^{-6}$
Tn*1*	A$^+$R$^-$ Tn*1*	ND	1.3×10^{-4}

Transposition into R388(Tp^r) was measured by mating *rec*A$^-$ donor strains containing R388, either pACYC184::Tn*3651* (*tnp*A$^-$ *tnp*R$^-$ Tn*3*) or pMB9::Tn*1031* (*tnp*A$^-$ *tnp*R$^-$ Tn*1*) and where indicated a third compatible plasmid carrying the complementing Tn*1* or Tn*3*, with a *rec*A$^-$ plasmid-free recipient strain.

* Fraction of Tp^r transconjugants receiving the transposon marker Ap^r; this include co-integrates and complete transposition products (Fig. 1*C*). (In all cases, except for the *tnp*A$^+$ *tnp*R$^+$ Tn*3* plasmid, the complementing plasmid was unable to transpose Ap^r.) We do not believe that the value of 8×10^{-7} in line 3 represents true transposition.

† Fraction of Tp^r transconjugants receiving the plasmid marker (Cm^r for pACYC184::Tn*3651* or Tc^r for pMB9::Tn*1031*).

That the same product from the *tnp*R region of Tn*1* and Tn*3* mediates both site-specific recombination at *res*, and repression of *tnp*A/*tnp*R expression, presumably by binding at or close to *res*, was confirmed by selecting *tnp*R$^-$ mutants derepressed for *tnp*A expression, which could then be tested for co-integrate resolution activity. Cells containing a R388::Tn*1031*::pMB9 co-integrate are Tc^r by virtue of derepressed expression of the Tc^r gene from the *tnp*A promoter (see Fig. 1*B*). Such cells were therefore transformed with hydroxylamine-mutagenized plasmid DNA (pDS4153; an Ap^r *tnp*A$^-$ *tnp*R$^+$ ColK::Tn*1* derivative). Ap^r transformants receiving unmutagenized DNA become Tc^s by virtue of *tnp*R-mediated repression whereas Ap^r transformants inheriting a *tnp*R$^-$ mutant of pDS4153 should remain Tc^r. About 10^{-3} of the Ap^r transformants remained Tc^r. Two of these were analysed in detail: plasmids the size of R388::Tn*1031*::pMB9 co-integrates and pDS4153 were observed. Isolation and subsequent characterization of the pDS4153-sized plasmids (designated pDS41531 and pDS41532) showed that the two mutants failed both to repress Tc^r and to resolve Tn*1031*-containing co-integrates in a *Sup*^{0} strain (that is, they appeared to be *tnp*R$^-$, by their inability both to repress *tnp*A-driven expression and to resolve co-integrates). In *Sup*D and *Sup*E strains, both mutant phenotypes were suppressed (to give Tc^s and co-integrate resolution) for each plasmid, whereas in a *Sup*F strain, no significant suppression of either Tc^r or co-integrate non-resolution was observed for either plasmid.

This provides further evidence that a single polypeptide from the *tnp*R region mediates both site-specific recombination and repression of *tnp*A/*tnp*R expression. We have previously suggested that *tnp*R protein could simply mediate both properties by binding at *res* if *res* contains promoters for *tnp*A and *tnp*R expression; sequence information and the known *in vitro* properties of the related $\gamma\delta$ *tnp*R protein support this idea[12,13].

MATTERS ARISING

Two major genes, linked to HLA and Gm, control susceptibility to Graves' disease

WE are pleased that Uno *et al.*[1] have extended to family material the finding[2] that variation in 'immunological networks', identified by HLA and Gm allotypes, contributes to Graves' disease susceptibility in a more than additive manner.

However, like Welsh[3] we regret the uncertainty created by the unspecific but clearly extensive selection of the families analysed by these workers. For example, if as they suggest two dominant alleles are involved, general offspring–parent correspondence between markers and disease, as in the family illustrated[1] is expected, but not reported. There is evidence that HLA-associated genetic susceptibility to Graves' disease is not dominant but involves the participation of two parental haplotypes[4], and in a series of 28 affected sib pairs, 68, 25 and 7% shared respectively two, one and no HLA haplotypes, more compatible with recessive or intermediate than dominant action of HLA-associated susceptibility[5]. In one large family having several cases of Graves' disease, HLA patterns were consistent with a dominant association[6] but Gm patterns (which have not been reported) are not. Generalization from small numbers of selected families regarding the genetic component in susceptibility to Graves' disease, and possibilities for predictions of risk to relatives[3], are inappropriate. In Caucasians, the associated HLA and Gm markers are found in 23 and 80%, respectively of the general population, but only ~1% of the general population and 5% of sibs of affected persons develop Graves' disease.

We are intrigued with the lack of association between specific allotypes and Graves' disease found by ourselves in Caucasians[7] and by Nakao *et al*[8] in Japanese individuals, although admittedly different allotypes were involved in the case of the Japanese and were less closely associated with the disease.

Sasazuki's laboratory previously reported[9] a strong association between Graves' disease and HLA-Dw12 (previously DHO), but now report instead an increase in HLA-DR5. This is rather surprising because DR5 seems slightly reduced in Caucasian patients with Graves' disease, and is instead associated with goitrous thyroiditis[5]. Moreover, HLA-DR5 does not exhibit cross-reactivity with HLA-Dw12-positive cells[10]. The authors need to resolve this discrepancy.

In contrast to the mouse, in which idiotypic determinants have been shown to be linked to C_H allotypic markers, no such evidence have been provided for humans, whose allotypic markers are located further down the Fc region[11]. Further work may reveal such an association; meanwhile it is worth considering the possibility that allotype- or isotype-specific networks of immunoregulatory cells may be involved in disease susceptibility[5]. Indeed, immunoglobulin subclass and allotypic restriction of the thyroid stimulating antibody have been demonstrated[12,13].

SASAZUKI AND UNO REPLY—We reported that two major genes, linked to HLA and Gm, control susceptibility to Graves' disease[1]. Of 30 Japanese families in which more than two first degree relatives were affected, only 15 families had at least two affected siblings, which we could analyse by the sib-pair method[2]. We did not conclude in any way that an HLA-linked disease susceptibility gene for Graves' disease was dominant. Recently we proposed[3] two genetic models for Graves' disease by analysing the same families using the affected sib-pair method[4]: (1) an HLA-linked recessive gene (gene frequency (gf) = 0.30) plus a Gm-linked recessive gene (gf = 0.10) with penetrance >0.60; (2) an HLA-linked dominant gene (gf = 0.08) plus a Gm-linked recessive gene (gf = 0.10) with penetrance >0.50. Due to the small number of affected sib-pairs, we could not distinguish between a dominant and recessive model for an HLA-linked Graves' disease gene. However, we can reject a dominant model if we analyse our data together with those of Farid and Bear[5]: of 43 affected sib-pairs, 27 shared two, 14 shared one and two shared zero HLA haplotypes.

There was not significant association between 30 probands with Graves' disease and Gm 1,2,21 (*a,x,z*) halotype which was reported[6] to be associated with Graves' disease. Rather in our study this haplotype was decreased in frequency (0.0860) compared with that in the Japanese population (haplotype frequency = 0.1575). Similarly, the present patient group did not show any association with Bw35(w5), which was reported to be associated with Graves' disease in the Japanese patients[7], where increased frequency of DW12(DHO) was also observed[8]. The present patients under study were selected from multiple case families whereas our previous study and that of Nakao *et al.* used unselected patients. This may partly explain the discrepancies observed for the statistical association of Graves' disease with the genetic markers, HLA and Gm, between our present study and those of Nakao *et al.*[6], Grumet *et al.*[7] and ourselves. This may also explain the observed discrepancy in the frequency of HLA-DR5 between our study and the report of Farid and Bear[5].

In any event, there are two distinct genes which have a major effect on susceptibility to Graves' disease and which are clearly identified by the genetic markers, HLA and Gm. Clarification of the immunological mechanisms controlled by these major genes awaits elucidation of the environmental factors which are crucial in triggering Graves' disease.

Positive selection causes purifying selection

IN their support of the neutral mutation hypothesis of molecular evolution, Li *et al.*[1] oversimplify the views of selectionists and use a specious logic that should not go unchallenged. They assert after Clark[2] and Milkman[3] that "selectionists believe that most nucleotide substitutions are caused by positive darwinian selection" and then using King and Jukes[4,5] as their authorities argue "in which case the rate of nucleotide substitution in functionally unimportant genes or parts of genes is expected to be relatively lower because the mutations in these regions of DNA would not produce any significant selective advantages".

I believe that the assertion of Li *et al.*[1] is an oversimplication. There are molecular evolutionists who are selectionists because they consider natural selection to be a driving force steering protein evolution[6-8]; however, such proponents of darwinian evolution of proteins are quite willing to have neutral substitutions occur at a high rate in pseudogenes, in the third position of the codons when the base changes do not cause amino acid changes[8], and in general in functionally less important regions of DNA.

The argument of Li *et al.*[1] is specious because it ignores two factors: (1) the time span for molecular evolution above the species level is in millions of years, not hundreds; and (2) the selection, which is positive darwinian selection when it increases the frequency of an allele in an evolving lineage, becomes stabilizing (=purifying or negative) selection after the allele replaces all others in that lineage. When these two factors are considered it follows that the nucleotide substitutions in functionally important parts of genes, as measured in distant pairwise comparisons such as those of Li *et al.*[1], could be primarily adaptive substitutions and still yield a slower evolutionary rate per nucleotide position than the neutral substitutions in functionally less important genes or parts of genes. For the short time span that an adaptive mutation is being fixed in a lineage by the positive darwinian form of natural selection, there could follow a very long time span during which the fixed mutation was maintained by the stabilizing form of natural selection. Thus over the total time span of many millions of years, the average evolutionary rate for such adaptive mutations could be relatively small. Nevertheless, the findings of Li *et al.*[1] on pseudogenes do not exclude the possibility that for certain important categories of base substitutions, for example, those that change amino acids, a relatively large proportion were fixed by selection rather than random drift.

LI *ET AL.* REPLY—Goodman accepts our view that random fixation of neutral alleles occurs at a high rate in such unimportant genes as pseudogenes or in general in functionally less important regions of DNA, but believes that natural selection is a driving force steering protein evolution. He suggests that a large proportion of amino acid substitutions in proteins are caused by natural selection. It is known, however, that the rate of amino acid substitution is also higher in functionally less important proteins or parts of proteins, as in the case of nucleotide substitution in DNA[1,2]. For example, fibrinopeptides A and B, which apparently do not have any biological function except for holding other polypeptides that later form a protein, show a rate of nucleotide (amino acid) substitution as high as that of pseudogenes[3,4]. The fact that amino acid sequence apparently does not affect appreciably fibrinopeptide function, and the mutation rate per nucleotide site is presumably the same for these peptides and pseudogenes, strongly suggests that the amino acid substitutions in fibrinopeptides are mainly due to random fixation of neutral alleles.

In functionally important proteins or parts of proteins, the rate of amino acid substitution is much lower than that in fibrinopeptides[1,2]. The neutralist's explanation for this is that these proteins have strong functional constraints, which cause many new mutations to be eliminated from the population, and only those mutations (amino acid sequences) that are functionally equivalent are incorporated into the genome[2]. In the neutral theory, therefore, the entire set of substitution data from pseudogenes to highly conserved proteins such as histone can be explained by the simple and realistic assumption that the mutation rate is the same for all segments of DNA (genes or parts of genes) but the proportion of fresh mutations eliminated varies with DNA segment and the higher this proportion, the slower the rate of gene substitution. Available data support this view, that is, fresh mutations are known to occur almost at random in the entire coding region of haemoglobin DNA[5], and any amino acid substitutions generally occur between two amino acids having similar biochemical properties[6,7]. However, if natural selection is the driving force for protein evolution, it would be difficult to explain the inverse relationship between the functional importance of genes and the rate of gene substitution[4]. Note that the rate of gene substitution due to darwinian selection depends not only on the mutation rate but also on the selection coefficient and population size[8]. In any theory based on selection these three factors must be considered.

Goodman's statement that we have ignored the two factors mentioned by him is unfounded. Our conclusion is based on a study of evolutionary change of genes for 80 Myr and on a due consideration of the effects of mutation, selection and random genetic drift. Note also that neutralists believe that adaptive evolution occurs by positive darwinian selection but a small proportion of gene substitutions is sufficient for this[9].

Jon Beckwith

MICHAEL Ruse's collection of ten essays covers a number of important issues in biology, biomedical science and the philosophy of biology. However, only one of these essays, 25 pages long, deals with the title question, is science sexist? Further, as I will consider later, his discussion of it misrepresents an important controversy over science and values. Let me follow this complaint with some praise for the author — this is probably the most accessible and lively writing by a philosopher of science I have come across. The book is entertaining, if often wrong-headed, and does present in clear fashion arguments on such issues as evolutionary theory, the recombinant DNA debate, genetic screening and medical views of homosexuality.

However, there is a current of reductionist thought which permeates most of these essays. For instance, in the first few chapters Ruse presents one of the most persuasive arguments in support of evolutionary theory — arguments which are particularly pertinent today with the attack on the teaching of evolution by creationists in the United States. (Ruse recently testified on behalf of the evolutionists in the Arkansas court case.) Yet he is so enamoured of the adaptationist explanation for biological phenomena that his arguments almost begin to turn against themselves. He describes lucidly how the "founder effect" accounts for the variations seen in Darwin's finches in the Galapagos Archipelago. (The founder effect refers to situations in which a small number of individuals of a species become geographically isolated from the rest and "founds" a new variant of the species with its own peculiar gene pool.) Yet the founder effect (among many other factors) could well lead to a number of variations which are not themselves a product of natural selection. If an adaptationist explanation is available for a phenomenon, it is presented as if it were almost proof of the explanation itself.

To take a strict adaptationist view trivializes evolutionary theory and turns it into a sterile enterprise. In fact, we are entering a rich period in the study of evolution as a result of advances in many areas of science, including protein chemistry, molecular genetics and palaeontology. This progress does not in any way lead to a rejection of the fundamentals of Darwin's theory, but vitalizes it with variations and new mechanisms some of which could not even be conceived of until recently.

Is Science Sexist? And Other Problems in the Biological Sciences. By Michael Ruse. Pp.299. Hbk ISBN 90-277-1249-2; pbk ISBN 90-277-1250-6. (Reidel: 1981.) Hbk Dfl.80, $42; pbk Dfl.32.50, $14.95.

Ruse also deals with the validity of Darwinian evolution as a genuine scientific theory using the criteria of Karl Popper. While I have no qualms about evolutionary theory, I do not feel that the defence in Popperian terms is very successful. As I will describe later, the use of falsifiability is problematic as many philosophers of science have recognized.

After covering some issues of interest to philosophers concerning the relationship between molecular genetics and Mendelian genetics, Ruse passes on to a discussion of genetic screening and its implications. By and large I found myself in agreement with the perspective in this essay. The fallacies of cost-benefit analysis of genetic screening programmes, the dangers of categorizing social and ethical problems as medical ones, the potential for discrimination against minority groups and the dangers of broadening the definition of genetic disease to include social behaviours such as homosexuality are pointed out. This is an excellent account for everyone working in the area of genetic screening. One complaint, however, which perhaps relates to the reductionist streak in this book: Ruse repeats the now discredited myth that XYY males exhibit antisocial behaviour, citing as his source a review by Borgaonkar and Shah, which apparently he has not read. For, in fact, these authors concluded that "The frequency of antisocial behaviour of the XYY male is probably not very different from non-XYY persons of similar background and social class".

Ruse's analysis of many of the issues in the recombinant DNA debate hits the mark, but his prejudice for reductionist science shows up again in such comments as "scientists [working with recombinant DNA] are finding out in the most basic way, precisely what makes the world work. . . .". Recombinant DNA is not a field of research; it is a tool for studying *certain* biological problems which are approachable at the level of the gene or of DNA structure. Because of its enormous power in studying these questions, this new tool has had a distorting influence on priorities in biological research. First, the study of genes in isolation from their general environment and from the cells and organisms in which they function provides answers to only a very limited number of questions. Further, most of the areas of biology which have to do with "what makes the world work" are ones to which recombinant DNA may not make major contributions. Can Ruse's attraction to "recombinant DNA research" be connected with his obvious interest in the explanations at the level of the gene found in sociobiology?

It is the arguments on the issue of sociobiology that seem the most strained in these essays. Ruse tries to put sociobiology on the same plane as evolutionary theory using analogous arguments about testability and falsifiability. Here the problems with falsifiability become clearer. Many might have thought that Marshall Sahlins's descriptions of the enormous variations in kinship systems in various cultures which counter predictions of sociobiology would have been a falsification of kin selection as applied to human societies. Instead, Sahlins's examples are either ignored or explained away by sociobiologists as due to unusual circumstances or to genetically aberrant societies, or *ad hoc* hypotheses are devised to incorporate them into sociobiology. What becomes clear is that a falsification to one person is an irrelevancy to another. Ruse is aware of this when he points out that just because "some people will not let a theory be falsified does not mean that the theory itself is unfalsifiable . . . ". But who decides when a theory has been falsified? To my mind, the conclusion that a particular set of data does or does not falsify sociobiology is a reflection of one's general stance on the issue rather than on some objective truth. In this light, Popper's concept of falsifiability seems vacuous.

While in earlier chapters Ruse points out the alternatives to evolutionary theory and convincingly dismisses them, in his discussion of sociobiology he barely mentions cultural explanations for human social behaviour. Again in contrast to the discussion of evolution, he does not indicate how one would go about distinguishing between the two explanations. It is simply his attraction to the adaptationist scheme which leads him to favour the genetic explanation. However, for complex human social behaviours, the environmental and genetic factors are so intertwined and so difficult to distinguish that I cannot imagine how this distinction can be achieved in the foreseeable future. Until that time the claims for evidence for the genetic model must be considered as no more than an indication of the biases of the scientists (and philosophers) who put forth the claims.

These arguments apply, of course, to the question of sex roles which Ruse discusses in his penultimate chapter. According to Ruse, one is not a sexist if one values positively the role of the female human being. This extraordinarily naive position ignores the broad cultural and institutional forms of power in society which perpetuate male domination. Sociobiologists place a heavy emphasis on sexual selection and on sex role division of labour and its evolutionary basis. These points are essential to the theory. The sexism of sociobiology does not lie in its conclusions, as Ruse would have us believe the critics have charged. Rather, the conclusions are a natural consequence of the fundamental assumptions which underly the whole sociobiological enterprise. For example, basic to E.O. Wilson's explanation of sex roles as they exist today is a reconstruction of human prehistory which describes the male as a hunter from early evolutionary times. He accepts the arguments of popularizers of palaeontology such as Ardrey and ignores the bulk of evidence which suggests that, for most of hominid evolution, we were vegetarians and fruit eaters. There are numerous similar examples in sociobiology where a social bias leads to the choice of explanation or of data which, in turn, are determinants of the conclusions of the theory. One has only to read Kropotkin's *Mutal Aid* to see that a different social perspective leads to a choice of different examples and thus to a totally different view of human nature.

This is a strange, contradictory and provocative book. While admitting that "one should [not] try to pretend that science can proceed divorced from ideology", Michael Ruse ignores the pervasive ideological influences on those attempts to use the biological sciences to explain human social behaviour. □

Jon Beckwith is in the Department of Microbiology and Molecular Genetics at Harvard Medical School.

Putting the environment back in genetics

Lindon J. Eaves

Cultural Transmission and Evolution: A Quantitative Approach. By L.L. Cavalli-Sforza and M.W. Feldman. Pp.388. Hbk ISBN 0-691-08280-4; pbk ISBN 0-691-08283-9. (Princeton University Press: 1981.) Hbk $25, £17.70; pbk $10.50, £7.50.

IN MANY applications of quantitative methods to human genetics it has been assumed, by default, that transmission is biological in spite of repeated criticism that environmental factors may simulate Mendelian inheritance. Historians and philosophers of science may wonder why the genetic theory of human differences has proved so powerful. Some of the credit must be given to the fact that the consequences of genetic inheritance found a precise mathematical form very early, in the work of such pioneers as Fisher and Wright. By contrast, environmental transmission models were inexplicit and devised to explain rather than predict.

The past ten years have seen a number of critical developments which have gone far to redress the imbalance of theory. Sociobiology arose because existing evolutionary theory seemed to run counter to those very human characteristics that evolution had established. Much of this work has been conservative, retaining at its centre the genetic basis of information transfer and attempting to show how such characteristics of higher organisms as sex, altruism, parental care, social organization and mate selection could evolve in a Darwinian universe.

Cavalli-Sforza and Feldman begin from a radically different position. They take the human capacity for learning and social interaction for granted and examine the many ways in which the dynamics and equilibria of human populations are modified when the rules of transmission are freed from their Mendelian straitjacket. Their work is a pleasing balance of theory and colourful examples.

They examine a number of ways in which cultural transmission may differ from genetic inheritance. In the simplest case, transmission may involve a single dimorphic cultural state passed from parent to child without the constraints which accompany Mendelian segregation. Such "vertical transmission" may often be confused with Mendelian inheritance but can generate a far wider range of dynamics and equilibria. The authors show, for example, the conditions under which cultural states may oscillate between generations if children react against the values of their parents. The theory is developed mathematically using assumptions and methods largely familiar to population geneticists. Cultural parallels of mutation, migration, selection and drift are examined, together with some models of assortative mating. Later chapters consider multi-state and continuous traits.

Cavalli-Sforza and Feldman recognize that transmission is not confined to the nuclear family. Information may be passed from teachers in the parental generation ("oblique" transmission) or in the same generation ("horizontal" transmission). In such cases only the type of social organization and communication network restrict the number of people influenced by a new idea, so the rates of evolutionary change increase dramatically. One possible consequence is the rapid spread of an innovation which has an adverse effect on fitness.

The authors are the first to admit that there is an element of unreality in treating cultural transmission independently of genetic inheritance, and there are other workers who have considered the joint effects of genetic factors and social interactions on the resemblance between relatives. Perhaps the only weakness of the present book is a failure to integrate the theory with other contemporary work in human quantitative genetics, much of which is just as concerned with the environment.

Part of the richness of *Cultural Transmission and Evolution* stems from the inclusion of illustrative examples, ranging from national differences in pronunciation, through the familial transmission of Buddhism, to the distribution of surnames. Data are used by Cavalli-Sforza and Feldman very much as they were used a century ago by Galton and Pearson, to illustrate rather than prove. There is little attempt to test and exclude alternative genetic hypotheses.

The long-term value of the book is likely to stem not from the data, however, but from the authors' ability to crystallize the elements of cultural transmission in a mathematical model which starts with a few simple assumptions. It offers, to biologists and behavioural scientists alike, an attractive demonstration of the heuristic value of model-building as a way of drawing together the more haphazard intuitions of the past and may make clinical and behavioural geneticists more sensitive to the ambiguities of their data. □

Supergiant behaviour

J.B. Hutchings

The Brightest Stars. Geophysics and Astrophysics Monographs, 19. By Cornelis De Jager. Pp.456. Hbk ISBN 90-277-1109-7; pbk ISBN 90-277-1110-0. (Reidel: 1981.) Hbk Dfl.140, $73.50; pbk Dfl.60, $31.50.

IN attempting to cover our current knowledge of the most luminous stars in nine self-contained chapters, Dr De Jager has set himself a formidable task. The recent pace of research has expanded the frontiers of this subject to an extent that no one volume can fully encompass. What the book does is cover, with examples and illustrative theory, the behaviour of all types of supergiant stars. Slightly surprisingly, it also sets out to deal with novae and supernovae.

The subject matter includes data from all wavelengths between X-ray and radio, on stars of all possible temperatures. Considerable space is given to describing observations and derived quantities typical of subgroups such as Of, Be, W-R, P Cygni stars and ζ Aur stars. Evolution, atmospheric structure and mass-loss are described in separate chapters, and the largest section deals with chromospheric, coronal and circumstellar dust phenomena.

It is perhaps too easy for one familiar with the subject to look for deficiencies or omissions. My main personal regrets were the lack of summarizing tables in many sections, the lack of coherence between some of the chapters and the omission of many of the observational details and uncertainties. A good bibliography of more specialized books, conference proceedings and reviews would also have been welcome.

Nonetheless, the book is fairly thorough in its coverage and it is hard to find much of importance that is left out. Theoretical sections accompany all descriptions of data, but are mostly given at the physical concept level; the book is not a reference source for applying or deriving rigorous models. The chapter on atmospheres is perhaps the exception here and is an excellent introduction to recent work. However some other topics are belaboured to the point of my wondering how important they really are.

The author has clearly made extensive use of other published material and diagrams. While this tends to override any particular bias, it leads to a somewhat variable depth in the treatment of different topics. Diagrams are generally reproduced from other work and often contain symbols or features not explained in the captions. There is a sprinkling of typos and grammatical curiosities, which do not detract seriously from the book's impact — one which occurs regularly is "criterium". I also spent some time looking for the fifth type of nova.

The most luminous stars are important as they are responsible for most of the X-rays, supernovae, enrichment of the ISM, star formation and optical radiation in a galaxy, but they are rare and constitute a small fraction of its mass. They are often the only individual objects we can study in other galaxies, and it is clear that we need to understand them more fully. This book provides a good background and overall description of their properties at a time when many new facts are being learned about them. ☐

Coming out on top

D.H. Everett

Chemistry in Two Dimensions: Surfaces. By Gabor A. Somorjai. Pp.575. ISBN 0-8014-1179-3. (Cornell University Press: 1981.) $48.50, £29.

THE George Fisher Baker Lectures at Cornell University have long had a reputation for excellence, and those which have subsequently appeared in print have been important milestones in the development of chemistry: they include the books of Alfred Stock, Monteath Robertson, Linus Pauling, C.K. Ingold, G. Herzberg, Paul Flory, Jack Dunitz, Herbert Brown and R.P. Bell. This volume by Gabor Somorjai will prove to be no exception.

The past 20 years have seen an explosive development of surface physics and surface chemistry, brought about as so often happens by major developments in experimental techniques. Today the tools of the surface scientist are represented by a bewildering and annually increasing number of acronyms. In this book, after an introductory chapter, some 20 such techniques are explained, and their application to the characterization of solid surfaces is outlined. The results of experimental work on the surface composition of alloys are then described and their theoretical interpretation discussed. Enrichment of the surface of alloys by one preferentially adsorbed component follows a pattern familiar in work on liquid–vapour and solid–liquid interfaces, and it is perhaps a pity that the opportunity was missed here to draw attention to the underlying unity of various branches of surface science. Thus the theories of the surface enrichment of alloys, published in the mid-1970s and presented in the book, are essentially identical with those of adsorption at the liquid–vapour interface originally developed for ideal systems by Butler in 1932 and for regular solutions by Schuchowitsky and Guggenheim in the 1940s, and applied in the 1960s to adsorption at the solid–liquid interface. The unfortunate impression left by the present account is that the theories described are recent developments aimed specifically at the solid–vacuum interface.

Two chapters on the structure of clean surfaces and of adsorbed monolayers on solids provide full and authoritative accounts of the voluminous literature on the subject. A discussion of the surface chemical bond and of energy transfer in gas–surface interactions provides a valuable introduction to the last third of the book, which is concerned with catalysed chemical reactions at surfaces. A general account of heterogeneous catalysis includes extensive and valuable tables of kinetic parameters characterizing the catalysis by metal surfaces of the hydrogenolysis of ethane, propane, *n*-butane, isobutane, the isomeric pentanes, several hexane isomers, *n*-heptane, benzene and a number of other hydrocarbons. Also tabulated are kinetic data on the ring opening of cycloalkanes, toluene hydrodealkylation and hydrogenolysis, the hydrogenation of olefins and aromatics, and the isomerization and dehydrocyclization of alkanes. These tables in themselves make the book an essential part of the literature on heterogeneous catalysis. Particular attention is then given to hydrocarbon conversion on platinum and to the catalytic hydrogenation of carbon monoxide; and a brief final chapter deals with photochemical surface reactions.

Gabor Somorjai has contributed much distinguished research to surface science. His enthusiasm and the authoritative position he commands in this field are apparent throughout this book. It cannot fail to become a classical text, the value of which will not be diminished by the rapid developments which will surely ensue in the future. Both as a wide survey of surface science, and as a source of critically assessed kinetic data on heterogeneous catalysis on metals, the book is most strongly recommended. ☐

D.H. Everett is Leverhulme Professor of Physical Chemistry at the University of Bristol.

Seminal secrets

R.J. Aitken

Male Reproductive Function and Semen: Themes and Trends in Physiology, Biochemistry and Investigative Andrology. By Thaddeus Mann and Celia Lutwak-Mann. Pp.495. ISBN 0-387-10383-X. (Springer-Verlag: 1981.) DM150, £32.

IN *Male Reproductive Function and Semen*, Mann and Lutwak-Mann have produced a highly authoritative treatment of a vast volume of literature relating to the production, composition and function of semen. The book is a sequel to the successful *Biochemistry of Semen and of the Male Reproductive Tract*, published by Methuen in 1964, and summarizes the important advances that have taken place in the field since that time.

There should be something in the text for any student, clinician or scientist interested in this subject. For the student, there is an extensive bibliography and a comparative approach which provides a fascinating insight into the diversity of reproductive strategies employed by different groups of animals.

For the clinician and scientist no page of this book should really remain unturned. Of particular interest to the former are sections on such topics as the assessment of semen quality, the cryostorage of spermatozoa and the biochemistry of seminal plasma in relation to andrological practice. For the research worker there are excellent, well-referenced methodological sections dealing with the logistics of experimentation in the male reproductive sciences.

To all proud possessors of a Y chromosome the final chapter on the influence of environmental factors on spermatogenesis and sperm function should be of special interest. The chapter covers a wide range of interactions, including those between addictive drugs, therapeutic agents, food additives, industrial chemicals and pesticides. The list of compounds interfering with male reproductive function is indeed alarmingly long and may go some way towards explaining the apparent progressive decline in the sperm densities encountered in normal fertile men from a mean of 100×10^6 cells per millilitre twenty years ago to a value of 50×10^6 at the present time. The role of such environmental hazards in the aetiology of male infertility is obviously in urgent need of assessment.

The emphasis of the book is clearly a reflection of the interests of the authors. Thaddeus Mann's contribution to our understanding of the biochemistry and function of semen has been universally acknowledged and his work has inspired a generation of scientists, including myself. One consequence of this interest in semen, however, is that the behaviour of spermatozoa once they have escaped from the seminal plasma and initiated their quest for the female gamete(s) is not given the same depth of treatment. The abilities of spermatozoa to migrate through the female reproductive tract and engage in the process of fertilization are of critical importance to the definition of fertility, yet neither of these important properties can be accurately predicted from the behaviour in sperm in seminal plasma.

A related problem is that the population of spermatozoa participating in fertilization *in vivo* spend a majority of their lifespan in a state of so-called capacitation. In contrast, a significant proportion of the studies reviewed in the extensive chapter on sperm biochemistry have been carried out on spermatozoa of uncertain physiological status suspended in simple, artificial media. The authors are obviously aware of this problem but conclude that it in no way detracts from the value and biological significance of the results. I wish I could share their confidence.

The layout of the book is excellent, although certain passages might have benefited from more extensive illustration, and I wish there had been a concluding chapter in which the authors' knowledge and experience could have been used to highlight the most significant recent developments. Nonetheless this is a major work by two highly distinguished authors; it should find a home on the bookshelves of anyone professing an interest in male reproductive physiology. □

Favourite recipes for the macrophage chef

S. Gordon

Manual of Macrophage Methodology: Collection, Characterization, and Function. Edited by H.B. Herscowitz *et al.* Pp.514. ISBN 0-8274-1222-6. (Dekker: 1981.) SwFr. 185, $65.

METCHNIKOFF drew attention to the specialized phagocytic capability of macrophages a century ago. Apart from their role in immunity against many important intracellular pathogenic organisms, the macrophages distributed throughout the body secrete numerous products responsible for inflammation, repair and injury. In addition, these cells retain differentiated traits *in vitro* and thus provide ideal material to study growth, membrane traffic, destruction of tumour cells and many other topics of interest to both cell biologists and immunologists.

Description of methods for studying the macrophage has traditionally been relegated to immunology texts, but several attempts are now under way to produce a separate, specific manual. This volume has arrived early and does contain much useful information, but is badly flawed by lack of a proper sense of where macrophage research is heading. Although sound prescriptions are given for the isolation of macrophages and study of some of their activities, exciting areas like H_2O_2 production and surface antigens are overlooked. Individual authors often turn to outmoded methods of cell characterization and elimination, by silica for example, rather than coming to grips with the problem of adherent cell heterogeneity. Thus, the implications of the discovery of the potent "antigen presenting" activity of dendritic cells, a minor contaminant of most macrophage populations, are not confronted. Other points of emphasis are irregular; interleukin-1 is well covered, but not CSF; the recovery of macrophages from spleen by enzyme digestion, a difficult but important procedure, is neglected; pinocytosis mediated by specific receptors is ignored; and so on.

Some authors give workmanlike assessments of procedures otherwise scattered in research papers. These include a catalogue of permanent cell lines with macrophage markers, culture methods for bone marrow precursors, cytochemical procedures for the light microscope, and the ever-useful detailing of Fc and complement receptor assays. Nevertheless, there are too many descriptions of everyone's favourite assay for microbicidal/cytocidal activity of activated macrophages and not enough assessment of their value. Readers will therefore find this book only moderately useful, and not sufficiently critical, integrated or comprehensive. □

In celebration of its fiftieth anniversary the American Institute of Physics has published a handbook for physicists of all persuasions, the *Physics Vade Mecum*. The book consists of 22 chapters containing useful formulae, numerical data, definitions and references pertinent to various fields, and is available from AIP Marketing Services, 335 East 45 Street, New York, price $25.

Chemical dynamics

J.N. Murrell

Potential Energy Surfaces and Dynamics Calculations for Chemical Reactions and Molecular Energy Transfer. Edited by Donald G. Truhlar. Pp.866. ISBN 0-306-40755-8. (Plenum: 1981.) $85, £53.55.

IN A rapidly developing area of science it is usually necessary to go to the primary literature to obtain details about the currently active experimental or theoretical techniques. The reason for this is not just that textbooks take some time to be published, but that authors have difficulty in deciding the opportune moment to write them. This book consists of a collection of original papers that were given at a symposium in August 1980. In that respect it provides an up-to-date perspective on this field and, in my view, a broadly balanced one.

Researchers interested in potential surfaces and molecular dynamics are concerned with understanding and predicting the results of collisions between simple molecules. The equations necessary for these predictions are well established but it is only in recent years that computational techniques have reached the level of providing, in many cases, reliable predictions. There are two stages in the calculation, both of which have seen recent advances: first, it is necessary to have accurate potential functions, and second they must be used for accurate dynamics.

There are three papers in the volume which give an overview of particular aspects of the field. These are on unimolecular dynamics, reactive scattering and non-reactive scattering. In addition there are 33 papers which deal largely with particular molecular systems. The contributions are generally of good quality and by respected authors, and thus I can thoroughly recommend the book for purchase by libraries and by active research workers in the field. □

What to tell the White House

The new White House Science Council is only a pale shadow of the old President's Science Advisory Committee; it should stay that way.

The King is dead; long live the King (or the Queen as the case may be)! Can this declaration, much cherished by historians keen to demonstrate the repetitivity of events, be applied to that curious political animal in the United States — the President's Science Advisory Committee? The committee (PSAC, pronounced *pea-sack*) was abolished in 1973 by President Nixon, as legend has it because it had become too uppish. Although many in the then administration, including even the Secretary of State, Dr Henry Kissinger, agreed with PSAC's most talkative members that anti-ballistic missile systems were then technically backward and always likely to be strategically ineffectual (and, for that reason, dangerous), the administration plainly did not want its negotiating position compromised by a bunch of fast and independently-talking academics, among whom members of PSAC were prominent. But now, after a decent interval, there is to be a science advisory council in the White House again (see page 637). PSAC having ceased to exist, it seems as if it has been necessary to reinvent it as the White House Science Council. Appearances, however, are misleading.

In its heyday, perhaps until the mid-1960s, PSAC was a remarkable institution. In many ways, it was a continuation into peacetime (made to seem threatening by the arrival of the first sputnik) of the camaraderie of the veterans of technological wars — the people who had set up radiation laboratories, Manhattan Projects and the like. PSAC in its early days was immensely influential because its members were influential, both in the academic community and with the government. PSAC seemed merely to have to wave its wand, and the federal government would agree that there should be a programme of curriculum development aimed at the improvement of science teaching in high schools, for example — ironically, the programme now finally dismantled in the Administration's budget for 1983. On other occasions, the committee lent powerful support, from outside the White House, to the executive functions of the Science Advisor as, for example, in the early 1960s when Dr Jerome Wiesner was battling with Mr McGeorge Bundy for an influence over United States policy on disarmament (and defence). Unlike most other advisory committees, PSAC seems not to have bothered to wait for a request for advice but would offer its opinions gratuitously, sometimes to people who did not want to hear. Always, PSAC gave the technical community in the United States the sense, but also the illusion, that there was an effective and publicly constituted channel by means of which account could be taken of raw technical opinion. What went wrong?

The doctrine that everything that President Nixon did must by definition be mistaken is a poor guide to the truth. While the Nixon administration may have been more afflicted by public disagreement about arms control policy than previous administrations, there is also something in the view that the virtues that made PSAC seem to the technical community to be exceedingly important were precisely those calculated to be a thorn in the flesh of the White House. The dilemma has been neatly described by Dr Edward J. Burger in his book *Science at the White House*, published last year. (For Professor Harvey Brooks's review, see *Nature*, 290, 635; 1981). Because many of the committee's pronouncements were unsolicited, they were not assured of the welcome they might otherwise have had. But when asked for its advice, PSAC would often provide its masters with an opinion which, even if entirely correct, could only seem to the embattled administrators to be unhelpful and even self-serving. Burger tells how the White House of 1970, anxious to do "something big" about public health but unsure of what, was disconcerted by a PSAC panel's view that a rapid growth of the force of practising physicians was unnecessary but that more money should be spent on biomedical research. The question remains unanswered whether a more pointed commentary on the options before the administration might have headed off President Nixon's "war" on cancer.

Administratively, Dr Keyworth's latter-day version of PSAC may be an improvement on the original. Even from the narrow view of the technical community, there is a balance to be struck between the prestige and independence of the old committee and the possibility that its successor may be listened to more attentively. The "bring back PSAC" campaign of the past nine years has been unreflective about this point. And even if, in the months immediately ahead, the chief function of the new science council is to strengthen Dr Keyworth's own position in the White House, that in the long run can do no harm. It may also help that the President's Science Advisor will be the sole channel for communication between the new council and the Administration. He, no doubt, is likely to be best placed to judge when this or that study can most effectively be put into circulation — and which had better be kept in a drawer. The other side of the coin is that the new council will not become a focus for the attention of the technical community, a legitimized whispering tube, and that even the members of the new council may from time to time suspect that they are being used.

The field of operations for the new council is less certain. From some remarks let slip in London last week, Dr Keyworth seems to think of the new council as a means of helping him solve some awkward administrative problems — making different uses of well-established national laboratories for example. But how? A high-level survey of the resources and capabilities of the national laboratories would benefit the whole technical community, even outside the United States, but Dr Keyworth seems to have more particular goals in mind. Does he want the committee to be his hatchet-man? Or, more machiavellian, does he hope that a committee which includes Dr Harold Agnew (once director at Los Alamos) and Dr Edward Teller (closely identified with Livermore) is bound to resolve the ancient dilemma of deciding which laboratory should go? The most obvious danger is that if the committee is too much used as a means of confirming administrative decisions, or as a means of sanctifying prejudices about what the national laboratories can and cannot accomplish, its reputation in the technical community will be unenviable.

Even without a single meeting to its credit, the composition of the new council cannot fail to excite prurient speculation. For the first time in almost a decade, the White House now has a science adviser who is not afraid to confess his enthusiasm for high-energy physics, and many of the members of the new council can be counted on the back him up. But should not Dr Keyworth be mixing in wider circles? The appointment of Dr Edward Teller to the council is similarly disconcerting. Nobody disputes Dr Teller's ingenuity or his zeal. That he should be thought of as a hawk is beside the point. But his inconsistency and intellectual impulsiveness are hardly assets for a new committee.

0028-0836/82/080635-01$01.00

A strategy for coal

The belief that indigenous coal production is strategically essential neglects lost opportunity.

Sir Derek Ezra, the chairman of the National Coal Board, is understandably cross to have been told (*Nature* 21 January) that the industry that he runs with such distinction should go out of business. His letter on page 642 makes a number of points that can readily be conceded. British coal-miners have indeed become more productive; output per man has increased by more than 50 per cent in the past 30 years, consonant with the further increase of three per cent in 1981. Many of the difficulties of the British coal industry can indeed be blamed on backward technology and inadequate investment over a substantial period of time; these were, after all, some of the reasons why the British coal industry was nationalized in 1947. It is also true that the Commission on Energy and the Environment, whose chairman is Lord Flowers, in its report last year supported the understanding between the coal industry and the British government that there should be a long-term programme of investment in British mines; the commission's report, *Coal and the Environment,* would no doubt have been more widely read and thus more influential if it had not been priced out of the market (at £23.00, from Her Majesty's Stationery Office) and then not distributed, on the grounds of cost, to those who might have reviewed it. But neither these arguments nor all the social and thus political arguments that attend coal-mining (not merely in Britain) are sufficient reasons for not asking whether Britain can afford its coal industry.

The central issue is the assumption that not merely coal, but British-mined coal, is strategically necessary now and in the future. The question arose earlier this year with the prospect (now happily averted) that the coal board's final offer to British miners on pay for 1982, widely advertised as the most it could afford, would nevertheless be scorned and some part of British industry once more brought to a halt. This annual tussle between the miners and the board, bodies otherwise entirely in concert in their conviction that public investment in British coal mines must be sustained, has in recent years been emphasized by the discovery that the cost of importing coal into Britain even from Australia is frequently less than that of the home-produced product. Sir Derek Ezra rightly argues that the price of job-lots of coal bought at the depths of a slump are not representative of the prices likely to be charged for it on the open market when prosperity returns again. This point was conceded, but perhaps too grudgingly, in the article now complained of. But who can suppose that if and when international prosperity returns, it will be possible to moderate miners' demands on the size of the British share that should come their way?

None of this implies that British miners are more grasping than miners elsewhere, or that miners as such are a cupiditous lot. The reality is rather that coal-mining is a dirty and dangerous job, especially in deep mines. Many people who do not work in deep mines say they would never do so. Some, perhaps many, who do work there would prefer to work elsewhere, given half a chance. Nobody blames them. Nobody should. So it seems probable that if and when prosperity returns, not merely will cheap job-lots of coal be harder to come by but so will miners — as in the mid-1960s, when Sir Derek's predecessor, Sir Alf (now Lord) Robens laid the foundations of the now conventional wisdom that British coal production at about the present rate (a third down since 1950) is a fixed point in the compass of the future. But mining, however well mechanized, remains labour-intensive, so that the return of prosperity to Britain (there are no mines worth speaking of in Northern Ireland, so that the nomenclature is permissible) will herald either the flight of miners from the mines or their demand to be paid even more above the odds or, more probably, both. To anticipate this is not to slander an honourable group of men but, rather, is to acknowledge their wit and their good sense.

The argument can even be turned around. In the tight communities of mining Britain, miners are acknowledged to be resourceful as well as stubborn. They do not cut the figures of people who are especially well paid. How could it be otherwise? Even if coal could be sold at the pithead for £100 a tonne (roughly the equivalent of the landed cost of oil in Britain), which is mercifully out of sight, coal-miners would still be producing less wealth than most of those who work in old-fashioned modern industries — motor-car manufacturing, for example. Their capacity individually to create as much wealth as those who work in truly modern industries — the design of microcircuits for example — is certain always to be small. So why not consider what the circumstances would be like if the part of the British work force that rightly prides itself on its special skill was working in a really productive industry? The hidden costs of the conventional British assumption that coal is strategically necessary, reflected not only in subsidies by taxpayers but in needlessly high prices, are certainly high. The opportunity costs of employing such large numbers of talented people on work characterized by its rigours and its hazards hardly seems wise. (The Commission on Energy and the Environment, no doubt because of its terms of reference, does not take up this question.) So why not follow some different strategy — buy fuel on the open market, or buy less labour-intensive ways of generating energys nuclear power stations for example. And none of this is new — W. Stanley Jevons argued, more than a century ago, that the time would come when coal-mining would no longer be competitive in Britain.

Mercury handcuffed

Liberalizing British telecommunications is uphill work because it goes against the grain.

All concerned seem to be making heavy weather of the attempt in the United Kingdom to liberate the telecommunications industry from the monopoly of the British Post Office (now known in this guise as British Telecom). For the best part of two years, the government was struggling with the unfamiliar problems of how in the abstract to define the conditions under which others than the public monopoly might be allowed to compete with it in the market place. Now, with the Telecommunications Act on the statute book, it is possible to buy telephone handsets retail in British shops without breaking the law. The instruments are those to which the monopoly has agreed to recommend that a licence can safely be given, on technical grounds. It has, by all accounts, been less easily persuaded that it should also fall in with the proposals by Cable and Wireless and Barclays Bank to set up an independent trunk telephone system. Called Mercury, the new system was announced last summer as the commercial alternative to British Telecom.

Only this week has an agreement been reached by the Department of Industry, the Mercury consortium and British Telecom. For some unaccountable reason, the parliamentary draughtsman of the bill supposedly ending the monopoly foresaw the possibility that British Telecom's network might at some point be used by communicators other than itself, but failed to provide that those licensed to communicate electromagnetic circuits to each other might use the public network if that were convenient. The public monopoly has therefore been legally within its rights, in the past few weeks, to agree that the alternative network could go ahead but that it would not be allowed to use its own interconnections, domestically (which is less important) and internationally. The trouble, for the monopoly, is that this legally valid position was politically untenable. The Department of Industry could not have lived with such an impasse. So, in the end, all three parties have compromised. British Telecom agrees that Mercury can use its connections, Mercury has agreed to pay a royalty to the monopoly — and the Department of Industry is probably in a mood to proclaim that competition is not the universal boon it is cracked up to be. What it should have done is to have defined the rules of competition and then to have deligated their interpretation to some regulatory body or the courts.

0028-0836/82/080636-01$01.00

New White House science council

Physics looms large on advisory panel

Washington

Dr Jay Keyworth, President Reagan's Science Advisor, announced last week that he is setting up a new White House Science Council to advise him on "science and technology issues of national concern" and of "changing perspectives in the science and technology communities".

The thirteen members of the new council will carry out tasks similar to those of the President's Science Advisory Committee (PSAC), which was abolished by President Nixon in 1973. However, unlike PSAC, which reported directly to the president, the council will report to Dr Keyworth as director of the Office of Science and Technology Policy.

Dr Keyworth in turn reports to the president's chief-of-staff in the White House, Mr Edwin Meese, implying a lower status to the Science Advisor's job than in previous administrations. So the Science Council, which is also distinct from the commission proposed by Congress in the Science and Technology Policy Act of 1976, will probably enhance Dr Keyworth's position on key policy issues.

The council, already being referred to as WHSC (or "wissick"), will therefore perform many of the functions of the President's Science Advisory Committee, established by President Eisenhower in 1957 in response to the launching of the Russian sputnik, and abolished by President Nixon in 1973 when some of its members took a public stand against his policies on anti-ballistic missiles and supersonic aircraft. But officials at the Office of Science and Technology Policy (OSTP) emphasize that whereas the committee formally reported directly to the president, WHSC will report to Dr Keyworth, OSTP's director.

There was no official comment on the balance of academic interests of the members of the new council, with its heavy emphasis on physics and the "hard sciences", and, apart from Dr Donald Fredrickson, the former director of the National Institutes of Health, no expert from the life or social sciences.

It was stressed, however, that individuals had been selected as much for their broad perspective and judgement on science policy questions as for their particular areas of expertise, and that each member had been hand-picked by Dr Keyworth "after a considerable amount of deliberation".

"We were concerned to have persons who can deal with the range of issues that we understand to be the greatest interest to this office," said OSTP staff member Dr Thomas H. Johnson, who will act as the executive director of the new council.

The chairman of the council will be Dr Solomon J. Buchsbaum, executive vice-president of Bell Laboratories in New Jersey. Dr Buchsbaum is a plasma physicist by training, and is an experienced governmental science adviser, having acted as chairman of the Defense Science Board under President Ford, and chairman of the Department of Energy's Energy Research Advisory Board under President Carter.

Vice-chairman will be Dr Edward Frieman, also a plasma physicist and a vice-president of the La Jolla-based consulting firm Science Applications Inc. Dr Frieman served as director of the Department of Energy's Office of Energy Research during the second half of the Carter Administration, and before that was deputy director of the Plasma Physics Laboratory at Princeton University.

Like Dr Buchsbaum and several other members of the new council, Dr Frieman has worked extensively as a scientific consultant to the Department of Defense. The military connection is also illustrated by the links which several members have with the Department of Energy's Los Alamos National Laboratory in New Mexico, where Dr Keyworth spent most of his professional career as a physicist before going to Washington last May.

Dr Harold Agnew, for example, was a member of the original Manhattan Project team that worked on the atomic bomb at Los Alamos. He joined the laboratory in 1942, became a director in 1970, and left to become president of General Atomic in 1978.

Dr Edward Teller, now emeritus professor of physics at the University of California and widely known as "the father of the hydrogen bomb", also worked at Los Alamos between 1943 and 1946, and acted as assistant director of the laboratory between 1949 and 1953. Dr George Cowan, a senior fellow at the laboratory, is a radiochemist specializing in nuclear reactions who, like Teller, worked at the University of Chicago before moving to Los Alamos in 1949.

According to a formal notice which appeared in last Thursday's edition of the *Federal Register*, the council will have a

Keyworth irked by national labs

One of the first jobs for the White House Science Council will be to hammer out a policy for the national laboratories supported by a federal government. And, according to Dr George A. Keyworth, President Reagan's Science Advisor, the national laboratories must be reorganized so as to provide more support for universities on the one hand and for United States industry on the other.

Dr Keyworth was speaking in London at the annual lunch of the Parliamentary and Scientific Committee, a regular event in the social calendar frequently used by British politicians to make promises or threats to their own scientific community. Dr Keyworth's irritation with the US national laboratories, made conspicuous by the blandness of the remainder of his speech, may cause managers of similar laboratories in Britain to fear that their own paymasters would follow Dr Keyworth's hint.

Dr Keyworth said that the original missions of United States national laboratories are frequently outdated, and that the "many billions of dollars" they receive from the federal government are not all used to "further fundamental knowledge or to address technologies pertinent to our national goals". He said that the laboratories have been "subject only superficially to external review" and that their missions had only rarely been reexamined.

Yet, according to Dr Keyworth, the national laboratories have a logical role as centres for cooperative research involving universities and could even help to make good shortages of teachers of engineering and computer science. He also wants the national laboratories to help reduce the present "unacceptably high resistance" to the application of research.

For the rest, Dr Keyworth gave his somewhat bemused audience a self-congratulatory account of how research and development, and federal support for basic research in particular, were second only to defence in the protection they had enjoyed in the two Reagan budgets. Nevertheless, he said, the scientific community would have to accept a greater degree of discrimination — and more responsibility for making discriminatory judgements.

On international collaboration, Dr Keyworth said that the United States had come to realize the limitations of what it could accomplish on its own, and the opportunities for collaboration with Europe and Japan. He thought that the next generation of high-energy accelerators would have to be built collaboratively, and that there were already opportunities for broadening the base of thermonuclear research programmes, at present too exclusively dependent on tokamak designs.

Although Dr Keyworth did at one point emphasize that he was not to be mistaken for Mr David Stockman, director of the Office of Management and Budget, he left many of his audience with the impression of a man still preoccupied with the small print of resource allocation. ●

0028-0836/82/080637-02$01.00

maximum of fifteen members, and will hold regular meetings up to six times a year. Some of the council's discussions may take place in public, since Dr Keyworth has said that he will comply with the requirements of the Federal Advisory Committee Act, which requires federal advisory committees to hold open meetings unless there is a specific reason that the meeting should be closed.

In addition to the members of the council, OSTP is compiling a list of about 100 other outside consultants from the scientific and industrial community who are expected to be called upon on an *ad hoc* basis to carry out specific studies.

Although both the apparent "military-industrial" bias, and the lack of social scientists — and women — have already received a certain amount of comment in the scientific community, reaction to the announcement of the new council has generally been favourable.

Mr William Golden, a New York banker who is treasurer of the American Association for the Advancement of Science, said last week that although the Science Council was "not as good as a presidentially-appointed group would be", it was better than none. He added that the individual members of the council were "first class", and that the new council should help strengthen Dr Keyworth's standing in the White House, since at present he was "not very high on the totem pole".

Council's members

Solomon J. Buchsbaum (chairman). Executive vice-president, Bell Laboratories

Edward Frieman (vice-chairman). Vice-president, Science Applications Inc.

Harold M. Agnew. President, General Atomic Company

John Bardeen. Emeritus Professor of Electrical Engineering and Physics, University of Illinois, Urbana

D. Allan Bromley. Henry Ford II Professor of Physics, Yale University

George A. Cowan. Laboratory Senior Fellow, Los Alamos National Laboratory

Edward E. David. President, Exxon Research and Engineering Company

Donald S. Fredrickson. Fellow-in-residence, National Academy of Sciences

Paul E. Gray. President, Massachusetts Institute of Technology

Robert O. Hunter Jr. President, Western Research Company

Arthur K. Kerman. Director, Center of Theoretical Physics, Massachusetts Institute of Technology

David Packard. Chairman of the Board, Hewlett-Packard Company

Edward Teller. Senior Research Fellow, Hoover Institution, Stanford University.

Turkish civil rights

Trials ahead

Dr Yeter Ögelman, a Turkish specialist in thermoluminescence and a lecturer in physics at Cukorova University, Adana, until her arrest and imprisonment on 16 May 1981, has now been released on bail. Her trial for helping to organize a women's rights group between 1975 and 1977 will, however, be resumed on 10 March. The prosecution is asking for a prison sentence of between 8 and 15 years.

Dr Ögelman's plight was exemplified some weeks ago when an article submitted for publication in *Nature* recorded her change of address and relocation in prison. The article will be published very shortly.

According to the Turkish authorities, Dr Ögelman's arrest and prosecution fall under the terms of article 141 of the Turkish criminal code. This lays down that those administering societies "with the purpose of establishing domination of a social class or overthrowing any of the established basic economic or social orders of the country shall be punished by heavy imprisonment from eight to fifteen years".

The code has already been used to ban the Turkish communist party. However, Dr Ögelman protests that, contrary to the authorities' accusations, neither she nor the "Progressive Women's Organization" was associated with the communist party. She says the women's organization was formed to campaign for women's rights and for improved education for women in Turkey.

Amnesty International has taken up Dr Ögelman's case, and says that her arrest contravenes the European Convention of Human Rights, of which Turkey is a signatory. That convention guarantees the right to freedom of expression and of association with others, although those rights may be prescribed by law "in the interests of national security or public safety". The Turkish authorities have denied that Dr Ögelman's arrest contravenes the convention.

Dr Ögelman was one of more than 170 people brought before the courts on 15 January, and was one of the lucky fifteen released on bail. Most of those on trial were allegedly members of the left-wing schoolteachers' association. Teachers' unions were banned nearly ten years ago, while the association was banned after General Evren's coup in 1980.

A number of academics have been arrested since the coup, and Amnesty International is unsure of their fate. A more general worry facing Turkish higher education is the bill announced last November that will further circumscribe university autonomy — for example, by giving the state control of senior appointments. The government's stated intention is to reduce the universities' tendency to act as foci for political disruption and violence.

Philip Campbell

European Space Agency

Peace declared

There is a new cheerfulness among the delegates to the European Space Agency (ESA). One sign of this, at last week's council meeting, is that the member governments have agreed on a resource budget for the next five years. The practical result is that it should now be possible to settle the annual science budget without waiting for unanimous agreement.

The council agreed to maintain the mandatory budget, which covers both science and the agency's basic running costs, at more or less its present level. Hence about 900 million accounting units (£540 million) will be spent over the next five years. But the director-general has promised to shift the balance in favour of science by making savings on the agency's overheads and by diverting interest earned on capital into the science programme. During the next three or four years, the science budget is expected to increase by about three per cent in real terms.

The increase is unlikely to make a substantial difference to the scientific community, which typically has to wait up to ten years for a particular kind of satellite. But the extra money may help ESA out of some of its difficulties.

The council's agreement is nevertheless something of an achievement. The level of the science budget has been hotly disputed for at least the past year, with some member states struggling to maintain their existing commitments and others, in particular France and Germany, arguing forcefully for a substantial increase. At the end of last year, agreement seemed beyond reach, largely because of Germany's wish to spend 20 per cent more on science after 1983. That would have involved all other member states increasing their contributions proportionately. In the event, Germany agreed to the five-year resource level with the proviso that discussions on the level of the science budget start again in 1984.

Last week's council meeting was notable for the formal announcement that Britain has joined the Ariane launcher programme as a fully-fledged member. Until now, Britain has contributed just over 2 per cent of Ariane's development costs through a bilateral agreement with France. The decision to contribute 3.5 per cent of the cost and to enter the programme proper is a recognition of the early promise of Ariane — and also of the diplomatic need to participate in other member' projects.

The quarrels of early last year seem thus to have receded. Then the British hankering after telecommunications and the French after the development of launchers polarized discussion of a ten-year plan for the agency proposed by Erik Quistgaard, the new director-general. The agency then had insufficient new applications programmes to fill the gap left when Ariane and Spacelab end development. During the past year, however, things have changed. Several new programmes have been approved including Ariane IV, the next stage of Ariane development; a Spacelab follow-on programme; L-sat, the heavy telecommunication satellite; and a microgravity programme. Pressure of work has taken precedence over the ten-year plan. But when the delegates next turn to the long-term strategy they may well find that the events of the past year have ironed out some of their earlier differences.

Judy Redfearn

Agricultural Research Council

Cuts tempered

The Agricultural Research Council is having second thoughts about its intended reorganization of agricultural research. The livestock industry may have persuaded the council to cut the Animal Breeding Research Organization at Edinburgh by a half, not four-fifths as originally intended. But the proposal to halve the cost of the Long Ashton Research Station at Bristol is to stand. The future of the two stations was the topic of a meeting last week between the council and representatives of the laboratories; final decisions will be taken at the end of March.

If the Edinburgh institute is partly reprieved, other council institutes will be on their guard. The council had hoped to save £3 million on its budget for 1983–84 by economies at the two establishments. Now, it will be £1 million short of its targets, and a call has gone to other institutes for self-imposed economies.

With the next financial year upon it, the council seems just now especially anxious to protect its interests in academic research. Last year, central government provided for only a 6 per cent rise on the wages bill but salaries rose by 7.5 per cent, leaving a shortfall of £0.8 million. As the council spends 95 per cent of its budget in its own institutes and units, and two-thirds of that on salaries, research budgets became unacceptably squeezed.

The council expects a more intense squeeze in coming years and fears a shortfall of £3–6 million in 1984–85. As grants to researchers in universities are to be protected and even increased, savings are being sought in institutes.

The council has nevertheless set its face against closing any institute that relies on commissions from the agriculture ministries for more than half its income. Other criteria used to decide which institutes to cut include the level of recent capital expenditure, future needs for facilities, overhead costs and the chances of successfully transferring work.

The proposal to cut the Animal Breeding Research Organization was based largely on internal assessments that had questioned the value of long-term animal breeding experiments. Originally, the council proposed to reduce the organization to only fundamental work, in particular on animal genetics. Representations from the livestock industry, however, seem to have rescued some breeding experiments, and the cattle blood-typing service may also now be retained.

Research on fruit is over-subscribed due to historical accident, according to the council — hence its decision to abandon pomology (apple-work) at Long Ashton and to transfer other work to the East Malling Research Station. Representations from strawberry, plum and mutant-apple growers, however, will now probably ensure some provision for research in these areas.

The council estimates that it will lose £0.5–1 million earned from ministry commissions. Other costs of the closures, including redundancy payments to approximately 220 staff, will initially increase the burden on the council's income. But much will depend on how many staff required to be mobile under the terms of their contracts can be redeployed in other institutes.

Judy Redfearn

Spain back to fold

The European Centre for Nuclear Physics (CERN) near Geneva has been in a pleasant spin for the past few weeks deciding how to react to an advance from the Spanish government. Spain wishes to rejoin (after a brief membership between 1961 and 1968) but there are few people at CERN who remember how such things are done.

In fact the last time a country joined CERN was 21 years ago, when the new adherent was Spain again. But they were early days for CERN, which is now an enormous institution with some 6,000 researchers and staff, massive experimental facilities for elementary particle physics and a £177 million annual budget to match. No official figures are available yet, but accession could cost Spain of the order of £10 million a year, something approaching a quarter of the present Spanish science budget.

The precise price which Spain must pay will be a matter for negotiation. Although members must pay in proportion to their gross national product, and Spain's is moderately high, it might be possible to negotiate step-by-step entry. However, all 12 members of the CERN council must agree to the terms, and there is an argument that Spain should pay entry fee in addition to the annual rate, to account for the fact that it will become part owner of the CERN accelerators. The lawyers are working on that, a spokesman said this week.

Robert Walgate

Polish universities

Trouble in store

Further clashes between Polish university students and the representatives of the ruling Military Council for National Salvation are feared in the near future, according to a Warsaw Radio broadcast last Sunday. In one of the regular morning briefings on the state of the country, an unidentified speaker said that classes have resumed just when the anniversary of the "so-called March events" is approaching.

The speaker was referring to the expulsion on political grounds of two Warsaw university students, by a decision of the then Minister of Education and Enlightenment, now president, Henryk Jablonski (5 March 1968). Three days later, a mass protest was held in the university grounds, claiming that the expulsion was contrary to university regulations since it had not been made by the rector. The students and some sympathetic academics were forcibly dispersed, but the incident triggered similar protests at universities throughout Poland — and ultimately resulted in mass dismissals and expulsions of students and staff, and the closure of several university departments.

Last year, the March anniversary was marked by a rally of students and academics in Warsaw, and by the formal rehabilitation of the "victims of 1968", including the philosopher, Dr Leszek Kolakowski. Even in the relatively liberal climate of 1981, the commemorations did not take place unopposed; the new "Grunwald Patriotic Association" was set up to hold a counter-meeting to praise government action in 1968.

Last Sunday's broadcast pinpointed growing official fears that young people have not yet accepted the changed situation in Poland and, in particular, the outlawing of the Independent Students Association (NZS). Formally, all protests are attributed to manipulation by hostile elements and political provocateurs. A government leaflet addressed to young people urges them not to be duped into involving the country in a civil war which would be a "tragedy for millions". There are hints in the media of attempts to defuse the tense situation by suggesting that all is not lost. An article in the daily *Zycie Warszawy* on the reopening of the University of Warsaw said that so far, no student had been expelled as a result of martial law — not even those at present interned. At the same time, the danger of taking part in demonstrations is stressed; a Gdansk commentator noted that those students arrested in the demonstration of 30 January would "have to say goodbye to their studies, at least for some considerable time".

Significantly, the announced agenda for the session of the Sejm (parliament), next Friday and Saturday, makes no mention of the new higher education bill.

US student loans

Lean prospects

Washington

Students from across the United States are planning to converge on Washington next Monday for a mass demonstration on Capitol Hill against cuts proposed in federal support for student loans. The demonstration is part of an intense, nationwide lobbying campaign by both students and university administrators aimed at persuading Congress to reject the Reagan Administration's cuts.

The Administration points to the escalating costs of the loan support programme, largely a result of recent increases in US interest rates to record high levels, and is seeking to reduce federal subsidies from an estimated $3,000 million in 1980 to $1,600 million by 1983.

Graduate students will be among those heavily affected by the cuts. Under the government's Guaranteed Student Loan (GSL) programme, graduates qualify for loans at a fixed 9 per cent interest rate; under new proposals from the Department of Education, they would now be allowed to borrow only from an auxiliary loan programme at significantly higher costs, with an interest rate of 14 per cent.

The result, according to figures prepared by the American Council on Education (ACE), is that a student who borrows $8,000 a year on top of previous undergraduate loans to make his or her way through graduate school could be paying off the money at a rate of about $500 a month for the succeeding ten years.

The presidents of almost all the nation's universities and colleges have loudly denounced the proposed cuts, claiming that by discouraging students from entering graduate training unless their sources of income are secure, the Administration is discriminating against groups who lack this security and undermining the long-term economic health of the nation.

Many feel that they had accepted last year's 20–25 per cent cuts in student loan support as their appropriate share of broader efforts to reduce federal spending. The new cuts, which in some cases would reduce federal subsidies by up to 50 per cent, have provoked the feeling that students are being asked to carry an unfair burden of Mr Reagan's economic policies.

The Reagan Administration's proposals are a mixture of economic pragmatism and ideological conviction that federal subsidies should be confined to the "truly needy". At present, under the GSL programme the government pays the 9 per cent interest on loans for both undergraduate and graduate students while they are at college, and also pays the difference between 9 per cent and the current interest rate for the remaining period of the loan.

Mr Terrel H. Bell, the Education Secretary, said in Washington soon after the budget proposals were announced that, as a result of soaring interest rates, the cost of administering the guaranteed loans, $367 million in 1977, is expected to rise to $3,400 million in 1983.

Reducing the eligibility requirements for the guaranteed loans and shifting the graduate students to the auxiliary loan programme would, claims the Administration, not only ensure that the available loans go to those most in need, but that the total costs to the federal government would be decreased by more than $2,000 million by 1987.

Many of the leading research universities, however, claim that such cuts would have a devastating impact. Dr Edward J. Bloustein, president of Rutgers Univesity in New Jersey, believes they would eliminate more than $12 million in aid received by about half of the 4,000 graduate students at his university.

According to figures produced by ACE, about 600,000 graduate students — half of those at present enrolled in US universities — are borrowing money under the GSL programme, in many cases close to the limit of $5,000 a year. At some of the nation's leading private research universities, the cost of graduate education, including living and tuition expenses, can be as much as $13,000 a year and university officials argue that, if they are forced to seek the more expensive loans, many students will either give up or delay their graduate education.

Given the extent of popular support for the student loan programme, the proposed reductions are expected to be strongly opposed by Congress.

In their defence, Administration officials reply that the present loan programme "encourages students to borrow regardless of financial need from their first year at school and can needlessly cause students to amass high levels of debt" which in turn allows "decreased reliance on family savings and student work". They also point to other initiatives, such as the efforts by the National Science Foundation to support graduate students in science and engineering, as proof that the government is prepared to continue support where it feels it to be necessary and appropriate.

David Dickson

Indian Antarctic expedition

Going for good

New Delhi

The Indian government, which sent its first expedition to Antarctica last month, is now actively considering the establishment of a permanent Antarctic base by 1985 or even earlier. Until then, the government intends to operate an unmanned weather station that will be linked via the polar Sun-synchronous satellite that India hopes to launch next year. The automatic solar powered weather station left behind by the recent expedition team will function for six months. It will be replaced in October, when it is hoped that a second team will arrive for a three-month stay.

Plans are also under way to set up an Antarctic Research Centre in India for training manpower, developing research programmes and working out the logistics of base support with the help of air force planes. The Department of Ocean Development is also planning to buy a ship for Antarctic work. One vessel under consideration is the 3,600 tonne *HMS Endurance,* the British Antarctic patrol ship, now for sale at a price of £1.5 million.

There are several reasons for India's new-found interest in Antarctica. Politically India does not want to be left behind China, which is planning to set up a manned station this year. The Antarctic programme is also considered essential to raise India's prestige among littoral states and to give it more weight in international forums on Indian Ocean affairs.

Although many of the Antarctic treaty powers have welcomed India to their club, India does not intend to sign the treaty immediately. It is, however, likely to stake territorial claims if the treaty members do not adopt the common heritage principle.

The Indian expedition was not advertised in advance for fear of adverse reactions from Antarctic treaty members. But, as it turned out, the reaction was quite favourable. The Indian team on board the chartered Norwegian ship *Polarsirkel* not only received weather reports from bases in Antarctica but also navigational help from the Japanese icebreaker *Fuji.*

The 21-member team led by Dr S. Z. Qasim landed on 9 January at a location 70° 3'S and 40° 7'E — an abandoned Soviet campsite. The Indians named the place "Dakshin (South) Gangotri". (Gangotri is the source of the River Ganges in the Himalayas.) The team left Antarctica after camping for 10 days, bringing back a tonne of rocks, several samples of ice and aerosols. One notable observation by the team was an unrecorded undersea mount in the Indian Ocean which has now been named Mt Indira after the Indian Prime Minister.

K. S. Jayaraman

Acid rain

Swedes persist

Brussels

Sweden is yet again to hold a major ministerial conference in an attempt to persuade its European neighbours to take the country's acid rain problem seriously. In June a two-week conference is to be held in Stockholm attended by 15 environment ministers from East and West — the sole country not being represented at a ministerial level being the United Kingdom. The first week of the conference will be devoted to examining the scientific evidence, and a political debate will follow.

It will be hard to separate science from politics. Many of the political arguments rely on demonstrating convincingly the direct link between sulphur dioxide emissions from the coal and oil burning industrial centres in Europe and the increase in the acidity and the presence of heavy metals in surface water in Scandinavia.

At a recent meeting in Brussels, organized by the European Environmental Bureau, many experts admitted that nobody was entirely clear about the precise mechanism between the cause and effect of acid rain. The evidence was there, though, to show that dramatic changes have taken place in the forests and lakes of Scandinavia even in the past two years. Research is now revealing evidence that sulphur dioxide emissions may also be linked to acidity in fresh water in Belgium and damage to forests in Germany.

While much of continental Europe is far richer in limestone than Scandinavia and is, therefore, less vulnerable to increases in the acidity of fresh water, the effect of the acid precipitation is nonetheless becoming apparent. The problem, the environmentalists argue is not just a Scandinavian one, and is already too serious to allow scientists the luxury of building up irrefutable evidence about the mechanisms involved before action is taken.

The political and economic opposition facing the Swedes seem unsurmountable. Eastern Europe is the source of much of the pollution — notably East Germany and Czechoslovakia. Each provides per capita sulphur emissions of more than 100 kg per year, well above that from West European states. The poor economic situation and energy problems of Comecon countries make it unlikely that they would consider investing money in costly anti-pollution equipment.

The 1979 Geneva Convention on long-range transboundary air pollution merely binds signatory states to "using the best available technology which is economically feasible". The Geneva Convention is still not in force, although 34 countries have initialled it. In the European Community. Greece, Belgium and Italy have so far failed to ratify.

Sweden's attempts to create the political momentum needed for change include the UN conference in Stockholm in 1972, the Helsinki meeting in 1975 and last year's acid rain conference in Gothenburg, but these initiatives have so far produced few concrete actions. Despite the ammunition provided by a study by the Organization for Economic Cooperation and Development, the European Commission has also remained far from convinced that there is a need to do anything more than monitor the situation. Many member states, like the United Kingdom, remain openly sceptical about the cause and effect of acid rain. **Jasper Becker**

Dutch elm disease

Northern drift

The British battle against Dutch elm disease has been virtually lost in the south of England and Wales, while the chances of success in northern Britain are slim, according to last week's annual review of the state of the disease by the Forestry Commission. In the south, perhaps 20 million of an estimated 29 million elm trees have been killed. And in the north, where beetles of the Scolytidae family have already crossed the north–south divide, the fight against the fungus carried by the beetle seems likely to be hampered by straitened local authority budgets.

The battle strategy recommended for the north of England is one which has failed in the south: sanitation felling. The objective is to cut down trees infected with the fungus *Ceratocystis ulmi* at an early stage and to burn the bark. The Forestry Commission holds out little hope for alternative control strategies now being tested — the "tree trap" technique that uses cacodylic acid (a tree-killing herbicide) to attract the beetles, artificial pheromones in conjunction with sticky traps and the fungicide Ceratotect, which can cure lightly infected elms. These techniques, the commission says, are only supplementary to sanitation felling, and are expensive.

So the labour-intensive technique of sanitation felling is recommended to continue in lightly affected areas. But local authorities must decide on what scale to battle. While control over the movement of elm wood is maintained by the Forestry Commission, the decision to divert funds to a felling campaign rests entirely with local authorities.

Where the elm population is isolated, active sanitation has proved highly effective. East Sussex County Council began its campaign in 1973, when signs of the disease first showed. Losses there have declined since 1979 and the worst may well be over. In Brighton, the casualty rate is down to 10 per cent. An important factor in the success of the campaign here was luck. The region is isolated and a good distance from the sources of infection — the docks of London, Bristol and the south. The council sees no reason to give up its campaign, and its budget for 1982 — £97,000 — will also cover planting costs.

East Sussex, however, is only a small pocket on a map of devastation. Authorities in the western counties have long since given up the fight and the area, with its dead elms and broken stumps, is described as looking like the Somme 65 years ago. The area to the north of Merseyside and the Wash, where conditions and species of elm are different, is described as "lightly affected", with as few as one per cent of elms lost each year. But the 5 million elms in the north of England, mostly wych elm (*Ulmus glabra*) have an important amenity value and constitute 10 per cent of total northern tree population. A majority of local authorities in the border regions of Scotland and northern England have ceased to exercise their powers of direct felling, some as long ago as 1977.

The problem is twofold. Once the disease takes hold, it is impossible to eradicate. Moreover, the elm bark beetle is no respector of regional boundaries and so far local authority programmes have been piecemeal. But the cost of sanitation felling falls entirely on local authority funds. Until 1979, the Countryside Commission for England and Wales supported local programmes, but has now been told that there is no prospect of diverting any substantial part of its funds to assist felling campaigns.

Support from central government has been equally unforthcoming. The Department of the Environment has its eyes set firmly over the horizon and describes the present problem as being on a "back burner", pointing to the Tree Council as the body maintaining a watching brief. The Tree Council, however, has been wholly independent, financially as well as administratively, since 1978. Hope for the future, as far as the Department of the Environment is concerned, lies in the development of elms resistant to the disease. Japanese elms are being planted in the royal parks.

The irony is that in seeking to avoid present costs, local authorities may well incur higher future costs. Merseyside County Council is having to spend nearly £250,000 to fell dead and dying elms that pose a danger to public safety. **Jane Wynn**

CORRESPONDENCE

Coal as Britain's security

From the Chairman of the National Coal Board

SIR — Your uncustomarily superficial and misleading article (21 January 1982, p.177) accuses the National Coal Board and the Government of being "in collusion to make water run uphill".

What, in fact, the NCB, the trade unions and the Government are jointly involved in is to ensure the security of future energy supplies for Britain by developing new and reconstructed collieries so that sufficient coal continues to flow to power stations, industry and homes and the country can continue, progressively, to diminish its dependence on oil.

Throughout the 1960s the coal industry was starved of capital when the policy of successive governments was to rely on plentiful supplies of cheap Middle East oil. Since the Middle East crisis of 1973–74 which changed that shortsighted strategy, investment in new and replacement mining capacity — essential to ensure continuity of production in an extractive industry like coalmining — has totalled £3 billion and continues at the level of more than £700 million per year. Because it takes about 10 years to develop a major new colliery, there is an obvious short-term financial burden of meeting heavy interest charges before coal production begins. That is one of the main problems the coal industry faces today and it is the legacy of earlier years of strategic neglect.

Your article scarcely recognizes the industry's considerable achievements. The coal we supply today is about two-thirds the price of oil and meets nearly 40 per cent of Britain's entire energy needs. Productivity in 1981–82 has so far risen by 5 per cent at the coal face and more than 3 per cent overall. After a previous period of decline, output at long-life collieries has increased by more than 7 million tonnes in the past three years. Exports have doubled for the third year running, and will reach about 10 million tonnes of coal and coke, which — with the addition of machinery exports by the manufacturing companies and mining consultancy services — will earn for Britain over £500 million in foreign currency.

Particularly in these times of continuing recession the British economy benefits from major purchases of goods and services from the National Coal Board — totalling £983 million in 1980–81 and having an overseas content of only £26 million (2.6 per cent).

It is astonishing to find you now repeating the same question that was asked in the 1960s of whether Britain needs a coal industry. An independent answer was recently given by the report of the Commission on Energy and the Environment which supported the coal indsutry's continuing large-scale investment. The Commission, whose chairman was Lord Flowers, stated that: "In both the energy and the environmental interest, we consider that greater stability of long-term planning is the essential pre-condition of successful modernization of the industry".

The Commission's conclusions on coal imports will also interest your readers: "We believe that most western governments will continue to find it sensible to favour indigenous coal supplies, and to be unwilling to jeopardize sensible long-run developments by allowing customers to play the market by allowing short bursts of low-cost imports of coal during temporary recessions. Most importantly, we recognize the social unacceptability of repeating in the last decades of the century the sequence of creation and then destruction of mining communities."

Commercial risk

SIR — There is surprisingly little discussion about the ways in which the practice of the biological sciences is changing as a result of the massive commercial investment in biotechnology. While some, like myself, may find the growing commercialization of bioscience depressing, there seems little one can do to stop its spread. But there is one aspect of the process that is an outrage, and bioscientists and the public agencies that fund them should unite to prevent its continuing.

Increasing numbers of scientists are giving their monoclonal-antibody-producing hybridoma cell lines to commercial companies and are then refusing to provide the antibodies and/or the cells to their colleagues. It can be argued that by relieving scientists of the time-consuming task of sending materials around the world, commercial distribution aids rather than hinders the distribution process. But in many cases the cell lines themselves are not made available and the cost of the antibodies is prohibitive if they are needed in large amounts.

The withholding of cells and antibodies for financial gain (or even worse, for selfish scientific advantage) is especially outrageous when these have been developed using public funds. Since it is the granting agencies that must ultimately pay for reagents that would otherwise be free and must endure the slowed pace of scientific advance resulting from the restricted exchange of materials, they should be leading the fight against such anti-science practices. Instead, it has been left to a few enlightened journals, such as *Cell* and *Immunogenetics*, to take up the cause and make free availability of cell (and DNA) clones and antibodies a condition of publication. Is it not time that the granting agencies followed suit and made free availability a condition of financial support?

The American Type Culture Collection was set up to provide a free cell banking and distribution service and has recently taken over the cell bank previously located at the Salk Institute, which contains a number of monoclonal-antibody-producing hybridomas. It would be helpful if this admirable facility were extended to include the distribution of those DNA clones and antibodies that are in especially heavy demand. There could then be no legitimate excuse for scientists not making their clones and antibodies freely available to their colleagues.

Free exchange between scientists is too important to be given up without a struggle. Without it, not only is efficiency sacrificed, but much of the joy of science will be lost as well.

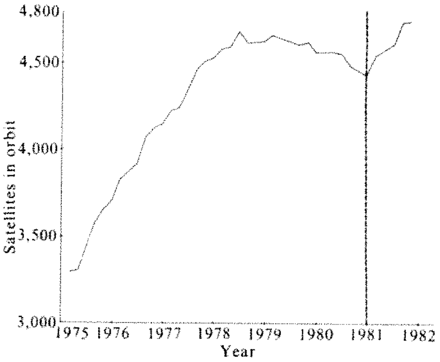
Spacecraft in orbit

SIR — The suggestion put forward by David Hughes[1] that the number of objects in near-Earth orbit has recently been decreasing, thus lowering the probability of spacecraft collisions, is seriously outdated. The data he presents, which stop at the end of 1980, show a small decrease in the number of objects in orbit from a peak in early 1978 until the end of 1980. However, during 1981 the number of objects in orbit rose rapidly, to an all-time high of 4,740 objects in October 1981 (NASA Satellite Situation Reports). From December 1980 to October 1981 the net increase of objects in orbit was 319. Most of these new objects resulted from two events. Early in 1981, 137 new objects associated with the US Landsat 3 satellite, launched in 1978, were detected. If this is another case of an exploding rocket motor, it indicates that the problem may not yet be solved. Another 118 objects associated with the USSR's Cosmos 1275 were identified shortly after its 4 June 1981 launch. If this rate of increase of objects in orbit continues, the first collision between satellites would be expected in the next 10–15 years according to calculations by Kessler and Cour-Palais[2]. A reversal of this trend is required to prevent a serious hazard to orbiting satellites in the twenty-first century.



Data from NASA satellite situation reports. The previous chart[1] finished where the dashed line indicates.

NEWS AND VIEWS

Whence so much ^{15}N?

from John F. Kerridge

An intriguing puzzle is emerging in cosmochemistry about the isotopic composition of nitrogen in the mixture of gas and dust from which the Solar System formed. Recent analyses of meteorite and lunar samples reveal enormous variations in the ratio of the stable nitrogen isotopes, ^{15}N and ^{14}N. The question at issue is whether the variations are due to nuclear processes in the Solar System, mass-dependent isotopic fractionation or mixing of 'solar' nitrogen with one or more alien components — material that has experienced different nucleosynthetic processing from the bulk of Solar System matter. Addition of alien material at levels up to about 5% is already well established from meteorite analyses[1]; but the nitrogen data, if the result of nucleosynthetic heterogeneity, could imply much greater levels of alien additions.

Observational data bearing on this issue are numerous and come from a wide variety of sources; a comprehensive review by Geiss and Bochsler will be published shortly[2]. I shall focus here on models advanced to account for those data, addressing specifically the value of protosolar ^{15}N/^{14}N inherent in each model. Isotopic components will be identified by their percentage depletion or enrichment in ^{15}N relative to the terrestrial atmospheric standard value, ^{15}N/^{14}N = 3.66×10^{-3}.

Geiss and Bochsler[2] propose that the dominant nitrogen component in the protosolar nebula had a value of +12%; virtually all natural samples could then be explained by admixture of a minor ^{15}N-depleted alien component, possibly pure ^{14}N. Occasional meteorites, such as Renazzo and Al Rais, with values up to +17%, are interpreted as containing interstellar molecules enriched in ^{15}N by ion–molecule reactions at temperatures below 100K in molecular clouds. Such reactions have been identified as the causes of the enormous fractionations observed for the hydrogen isotopes in interstellar molecular clouds, but little corresponding astrophysical evidence exists for nitrogen and it is debatable whether adequate ionization of nitrogen-bearing species occurs in the interstellar medium. The secular increase from <-21% to +12% observed in nitrogen trapped during the past 3–4 Gyr in lunar surface samples is ascribed to mixing of solar wind characterized by a constant nitrogen value of +12% with an outgassed lunar component rich in alien ^{14}N, whose mixing ratio decreased with time. There is strong evidence from the analysis of lunar samples, however, against the presence of such a hypothetical non-solar wind nitrogen component, and, furthermore, indigenous lunar nitrogen appears to have a composition close to zero rather than <-21% as predicted.

A recent analysis of nitrogen in the Allende carbonaceous meteorite, by Thiemens and Clayton[3], has been interpreted in terms of a major protosolar value of -3% and a minor alien component of -9%. A -3% component is also observed in meteorites known as enstatite chondrites, which many believe to contain nitrogen condensed directly from the nebula at relatively high temperatures with minimal isotopic fractionation. It must be stressed, however, that no host phase for nitrogen in any meteorite has been firmly identified with relict nebular material, so the possibility of secondary fractionation is always present. The alien nature of the -9% component is supported by correlations with an alien xenon component recently identified by Frick and Pepin[4]. Thiemens and Clayton interpret meteoritic values up to about +4% as due to mass fractionation during nebular condensation, and the <-21% lunar value as due to fractionation of the -3% component in an early solar wind. The apparent secular increase recorded by the lunar surface samples is ascribed to nuclear reactions, that is, production of ^{15}N, in the solar wind reservoir. Problems concerning production of ^{15}N in the Sun will be discussed later; specific difficulties of the Thiemens and Clayton model are its failure to account for for the +17% meteoritic values and the lack of evidence that mass fractionation in the solar wind could reduce a value of -3% to <-21%.

My own model[5] of this process which yields a protosolar ^{15}N/^{14}N of <-21%, assumes that the earliest apparent solar wind value characterized the solar convective zone at that time, thereby establishing an upper limit to the protosolar value. The apparent secular increase in the solar wind value is ascribed to nuclear production of ^{15}N in surface regions of the Sun; meteoritic and planetary values are attributed to mass fractionation during formation of condensed species at very low temperatures, though addition of ^{15}N-enriched alien material is a reasonable alternative. The main difficulty with this model, and the preceding one, stems from the considerable body of observational evidence constraining nuclear production of ^{15}N in the Sun.

The present γ-ray flux from the Sun indicates a level of nuclear activity far too low to generate adequate ^{15}N; the lack of evidence for significantly greater solar flare activity in the past similarly precludes greater ^{15}N production then; and certain other nuclides, whose production would accompany that of ^{15}N, are not observed. Another problem concerns the temperatures at which adequate isotopic fractionation could occur to explain the meteoritic and planetary data; at such low temperatures reaction or exchange between neutral species, as customarily invoked for nebular condensation, is implausible. Ion–molecule reactions can again be invoked, but with the same reservations as discussed earlier. As an alternative to fractionation, addition of alien ^{15}N-rich matter cannot be ruled out but the scarcity of ^{15}N in the interstellar medium reduces the plausibility of such a component.

John F. Kerridge is in the Institute of Geophysics and Planetary Physics, University of California, Los Angeles, California 90024.

0028-0836/82/080643-02$01.00

Finally, there is a class of models based, like the previous one, on solar wind data, but which ascribes the apparent secular change to 'contamination' of the Sun's convective zone by interstellar matter. The most detailed of these models[6] proposes an early addition of material from a planetary nebula rich in ^{14}N to a proto-Solar System consisting initially of +17‰ material. This would have resulted in a value of <−21‰ for the solar convective zone which has subsequently evolved towards the bulk solar value of +17‰ as underlying material replaced ejected solar wind. Meteoritic and planetary compositions may be interpreted as in the Geiss and Bochsler model. A general problem with 'contamination' models is the large apparent size of the actual convective zone; this would require massive additions of alien material for which evidence should be, but is not, found elsewhere.

A potential weakness of models relying on solar wind data lies in the identification of solar wind composition with that of the solar convective zone. Persuasive arguments have been advanced by Geiss and others (see, for example, ref. 7) that such equivalence does exist, but recent spacecraft measurements of solar flare composition suggest otherwise. Mewaldt and co-workers[8] have reported an isotopic composition of solar flare neon which is distinctly different from that in the solar wind, and they also argue against mass fractionation in the flare as an explanation of the difference. Arguments against fractionation in the solar wind are equally strong, but the flare measurements are at least a warning against identifying solar wind composition with that in the convective zone.

Clearly, an unequivocal estimate of protosolar $^{15}N/^{14}N$ is not yet in sight. Indeed, the observations discussed above may signify isotopic heterogeneity for this element in nebulae. It is equally clear that the apparent secular change in solar wind $^{15}N/^{14}N$ lacks a satisfactory explanation. The issue of protosolar $^{15}N/^{14}N$ may soon be resolved by the Galileo mission to Jupiter. No net fractionation should have accompanied accretion of nitrogen by Jupiter, and all nitrogen should now be present as ammonia; this simplifies the interpretation of the mass spectrometric data that will be gathered. It is to be hoped that the mission will not succumb to the budget-cutting zeal of the present US administration. If not Galileo, who? If not now, when? □

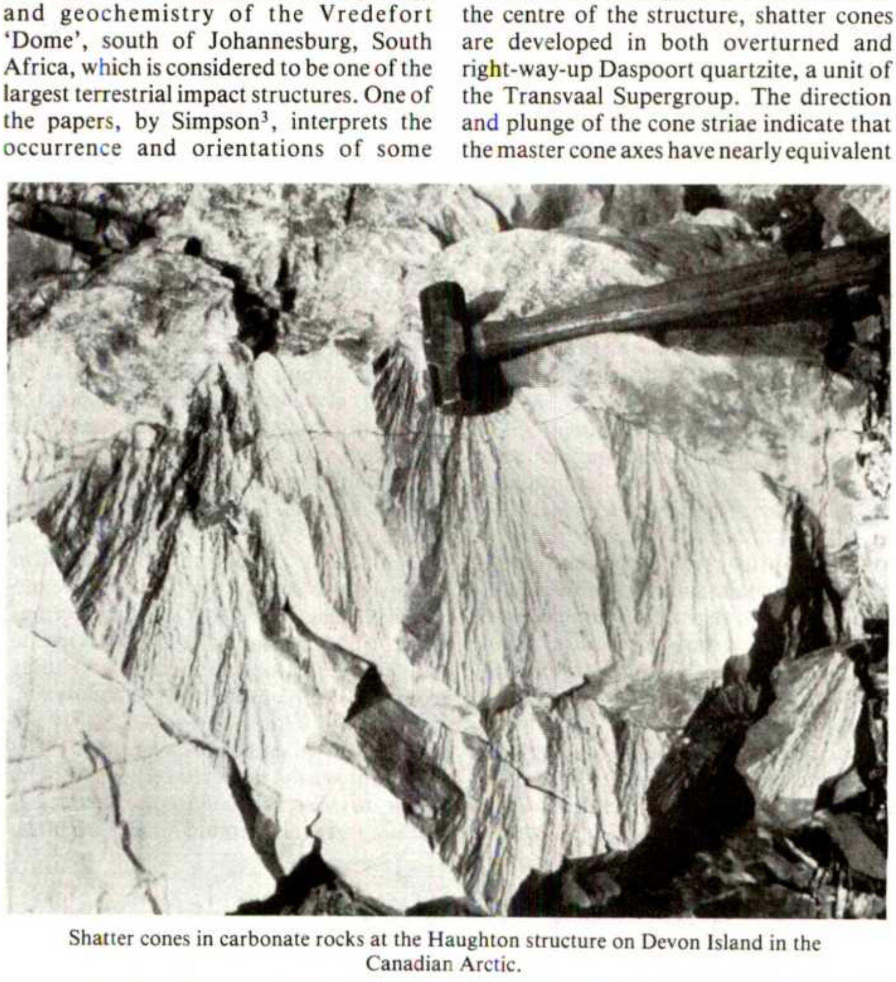
The Vredefort structure still not understood

from Richard A.F. Grieve

THE recognition that impact cratering was a fundamental geological process in the evolution of early planetary crusts[1], together with recent suggestions that faunal extinctions at the Cretaceous–Tertiary boundary may be linked to a major impact event[2], have heightened interest in the terrestrial record of impact cratering. Approximately 100 known terrestrial structures larger than 1 km in diameter are considered to be of impact origin. One criterion for their recognition as such is the occurrence of shatter cones — cone-and-cup structures, with striated surfaces radiating from parasitic horse tail-like half cones on the face of a master cone and varying in size from less than 1 cm to as much as 10 m (see the figure). These cones, as well as microscopic planar deformation lamellae in minerals, solid-state glasses and high-pressure mineral polymorphs, are characteristic of shock metamorphism. They have been reproduced in shock experiments and in nuclear explosions, occur at small terrestrial craters with meteorite fragments, and have also been observed in meteorite and lunar samples. In a recent issue of the *Journal of Geophysical Research*, there are six papers dealing with various aspects of the geology and geochemistry of the Vredefort 'Dome', south of Johannesburg, South Africa, which is considered to be one of the largest terrestrial impact structures. One of the papers, by Simpson[3], interprets the occurrence and orientations of some shatter cones at Vredefort as precluding an impact origin.

The principal morphological elements of Vredefort are a central core of Archaean basement with an 18 km radius, a 17 km wide 'collar' of steeply dipping or overturned sedimentary and volcanic rocks of the Witwatersrand and Transvaal Supergroups, and a 20–30 km wide outer synclinorium containing members of the uppermost unit of the Transvaal Supergroup. If an impact feature, Vredefort would correspond to what is known as a complex structure, where the original excavated cavity has been modified by uplift in the centre, producing the central core, the penetration and overturning of the stratigraphically higher strata of the 'collar' rocks and the downdropping of the outermost regions to give the peripheral synclinorium. Simpson, however, points to two localities which suggest that at least some shatter cones appear to post-date the overturning of the 'collar' rocks. Such an interpretation conflicts with predictions of an impact model, in which shatter-coning occurs during passage of the shock wave, before uplift of the core and overturning of the 'collar' rocks.

At the first locality, about 40 km west of the centre of the structure, shatter cones are developed in both overturned and right-way-up Daspoort quartzite, a unit of the Transvaal Supergroup. The direction and plunge of the cone striae indicate that the master cone axes have nearly equivalent



Shatter cones in carbonate rocks at the Haughton structure on Devon Island in the Canadian Arctic.

0028-0836/82/080644-02$01.00

vertical orientations, regardless of bedding orientation. The overturned and right-way-up beds are separated by a fault, which strikes radially towards the centre. If, as suggested, this fault is related to the uplift of the central core, then the similar orientations of the master cone axes indicate that at least one generation of shatter-coning took place after the overturning of the 'collar' rocks.

At the second locality, shatter cones occur in an indurated fault breccia, which lies 40 km north of the centre in a fault zone that is part of a series of faults which downthrow overturned Daspoort quartzite beds. As there is no evidence of shatter-coned clasts in a non-shatter-coned matrix, shatter-coning took place after breccia formation. Furthermore, the faulting is thought to have occurred simultaneously with or after the overturning of the beds, so the shatter-coning is post overturning. Simpson's interpretations of these shatter-coned localities are at odds with an impact origin for Vredefort and, by implication, they cast doubt on shatter cones and other shock features as criteria for the recognition of impact structures.

What then are the alternatives? Simpson suggests the cones resulted from shock waves produced by internal tectonic processes. But the problem with such an explanation is that experimental data indicate that shock features are formed only at pressures of tens to hundreds of kilobars. Shatter cones, in particular, appear to require pressures of 20-60 kbar[4]. Even if such pressures could be maintained in the Earth's crust, how could they be produced? Mechanisms involving a deep internal explosion fail to generate such pressures, because the mechanical coupling efficiency between shock waves in a gaseous medium and rock is low (probably less than 1 per cent).

Previous measurements at about 50 sites by Manton[5] indicated that virtually all shatter cones, when restored to their pre-overturning position, point to the centre of Vredefort and define a focus, or point of origin, for the shock wave some 13.5 km above the base of the Witwatersrand. This corresponds roughly to ground zero at the time of cone formation. Perhaps these two new occurrences are exceptions. Rare cases of cones which do not point to the centre are known from other structures and the formation of occasional inverted cones is predicted in one hypothesis of cone formation involving differential shock impedance of strata. The occurrence of cones in a fault breccia and not in the associated quartzite is certainly unusual. Shatter cones are generally best developed in fine-grained, structurally homogeneous rocks such as carbonates and quartzites and not in inhomogeneous rocks such as breccias. The interpretation of the relative timing of the faulting in the two areas with respect to core uplift is critical. In considering the preservation of coesite and stishovite, high-pressure polymorphs of quartz, in psuedotachylite, Martini[6] noted that some deformation associated with Vredefort is related not to impact but to earlier and normal tectonic action. The injection of psuedotachylite veins into the fault breccia at the second shatter cone locality could be interpreted to indicate that at least some of the faulting predates the shock event.

Whatever the explanation, the bulk of the shatter cone evidence from Vredefort still appears to favour an impact origin. It has taken some twenty years of documentation, experiment and theory to establish the impact origin of shock-metamorphosed structures and to appreciate the complexities of the impact process. The new evidence from Vredefort is enigmatic. It must be weighed against the wealth of other evidence and, in the present author's opinion, is insufficient to invalidate the interpretation of Vredefort as an impact structure and the use of shatter cones and other shock features as indicators of meteorite impact. □

Carbon dioxide and climate: has a signal been observed yet?

from Starley L. Thompson and Stephen H. Schneider

In a recent paper Kukla and Gavin of the Lamont-Doherty Geological Observatory[1] examine recent and historical data on the extent of polar ice and snow, hoping to detect changes that might be a signal of warming caused by the build-up of CO_2 in the atmosphere. This and other new work which looks not only at the effects of changing carbon dioxide levels but also at other gases capable of creating a 'greenhouse effect', make it necessary to consider seriously whether the question posed in the title can now be answered in the affirmative.

Kukla and Gavin compiled recent data for sea ice in the Southern Hemisphere for the period 1973–1980 from weekly charts prepared using satellite IR, visible and microwave observations, as well as conventional surface observations. They selected the late spring and summer periods for examination, for the energy balance model of Ramanathan *et al.*[2] suggests that the largest CO_2-induced changes would occur then (though the model was actually based on snow cover rather than sea ice change). They found that the mean extent of the summer ice decreased from 8.2×10^6 km^2 in 1973 to 5.7×10^6 km^2 in 1980. However, as sea ice varies naturally to a comparable degree the decrease is not necessarily indicative of CO_2-induced warming. Indeed Kukla and Gavin note that the area of ice increased in 1981.

Several atlases published before 1970 report the extent of Southern Hemisphere sea ice to have been greater than that observed during the 1970s. However, as Kukla and Gavin carefully explain, the historical and the recent sets of data are not necessarily comparable as the extent of the ice recorded in the atlases was taken from relatively few surface observations. Observational biases could exist which would give the false appearance of a long-term trend.

Arctic data are even more equivocal. Kukla and Gavin do not find that similar observations of Northern Hemisphere sea ice indicate that there was less ice now than in the 1930s. Satellite-derived records of summer snow-cover do not show a decrease either, although recent positive surface temperature anomalies at 'selected latitudes' in the north have been associated with the belt of melting snow in spring and summer, and are thus 'consistent with' the Ramanathan *et al.* model predictions for CO_2 increase.

Kukla and Gavin suggest that "highly variable components of the climate system such as snow and pack ice fields" be given priority in the search for early signs of a CO_2 effect on climate, a conclusion consistent with Manabe and Stouffer's model[3], whose sensitivity to CO_2 depends heavily on concomitant sea ice changes. Although high variability of some climatic component may imply high sensitivity to external forcing (for example, increased CO_2), such variability unfortunately also makes it difficult to detect a CO_2 signal — even a large one — because high variability usually implies a high noise level as well. The best 'precursor indicators' are, of course, those having a large signal-to-noise ratio.

Chlorofluorocarbons (CFCs)[4], methane

and nitrous oxide[5] are, like CO_2, effective absorbers of IR radiation and thus could also help to create a greenhouse effect.

The sum of all trace greenhouse gases has even been referred to as 'virtual CO_2 concentration[6]'. Lacis *et al.*[7] at NASA's Goddard Institute for Space Studies (GISS) recently used a one-dimensional, radiative–convective model to estimate the global equilibrium and transient warmings expected from trace gas increases between 1970 and 1980. Interestingly, the computed equilibrium warming from CH_4, N_2O and CFCs combined was 0.1 °C, nearly as large as the 0.14 °C warming computed from the CO_2 increase during the same decade. There remains, of course, some uncertainty, even in the purely radiative calculations. For example, the equilibrium sensitivity of the Lacis *et al.* model to a 2 p.p.b. (parts per 10^{12}) increase in CFCs was 30 per cent more than that in a calculation published by GISS scientists only two months earlier[8]. The more recent result, +0.65 °C, now agrees more closely with Ramanathan's[4] calculation of +0.9 °C but the above discrepancies remain to be resolved. By allowing for the transient effects from thermal inertia of the oceans[9,10], Lacis *et al.* reduced their calculated equilibrium expected warming during the 1970s by about one-half.

The GISS group results come from a mathematical climate model which has an equilibrium global surface temperature sensitivity of about 3 °C for a doubling of CO_2 concentration. This is within the present 'consensus' estimates (1.5–4.5 °C)[11]. Some still believe that these estimates are much too high[12,13]. Idso, in particular, strongly believes that 'natural experiments' yield an 'empirical response function' some orders of magnitude smaller than the consensus models although he may have neglected some categories of energy flows and storages. In our opinion, it has been convincingly shown[11,14] that the neglect of horizontal heat flux, heat storage and total atmosphere/surface energy budget has caused Idso's low estimates of global, equilibrium sensitivity to a doubling of CO_2. We do, however, agree that tentative model assumptions demand empirical verification, but such comparisons between models and observations must be properly applied.

An example of empirical verification of a climate model is given in a recent study by Hansen *et al.*[8]. A simulation using CO_2 forcing was compared with the historical temperature record to give a 'direct' verification of the CO_2 sensitivity of the model. One difficulty with this approach is distinguishing what is still a small CO_2 signal from background noise. In addition, their model was based on assumed solar and volcanic forcings whose combined effects were matched to the observed temperature record by adjusting empirical coefficients. This 'tuning process' can engender confidence when the results are statistically significant, but this has yet to be shown. Another direct verification approach would be to compare palaeoclimatic temperature proxy data with the results of a model forced with observations — actually reconstructions — of natural long-term CO_2 variations. Such variations have recently been confirmed by Neftel *et al.*[15] to have occurred over at least the past 40,000 yr. Problems with this approach include estimates of global temperature and CO_2 concentration which are subject to large errors and the necessity of accurately accounting for additional climatic forcing factors such as surface albedo changes.

Empirical verification may also be 'indirect' — model performance may be compared with a surrogate 'geophysical experiment' not involving CO_2 change, such as the annual cycles of solar radiation and temperature[3,16]. Difficulty remains in evaluating the extent to which a surrogate experiment is applicable to the CO_2 forcing case. Both of these empirical methods of verification need to be, and have been[11], used to test the 'consensus models'.

The average standard deviation of annual global temperatures within individual decades over the last century is about 0.1 °C. For this reason the estimate of warming during the 1970s given by Lacis *et al.*, despite being comparable with that observed, is too small to engender real confidence in the model results. However, Lacis *et al.* believe that, by 1990, temperature rise signal from the *combined* trace greenhouse gases should stand out clearly from the background of natural climatic variability. This belief assumes, of course, that current trends in CO_2 and other trace gas concentrations continue, and that the sensitivity of present climate models to such increases is reasonably correct. A global warming of 0.2–0.3 °C during the 1980s, as Lacis *et al.* predict, would have a fairly small probability of chance occurrence, although it is not unprecedented. An increase of this magnitude occurred in the 1920s (for example, see Fig. 3 of ref. 8), which presumably was not a CO_2-related event. Furthermore, extrapolations of present trends of trace gas increases past the year 2000, particularly those for CO_2 based on the assumption of large coal use, have been strongly challenged on economic grounds[17,18]. Thus, because a doubling of CO_2 from massive coal use in the near future is questionable, but a further 25–50 per cent increase from petroleum and natural gas combustion is possible, we feel even more strongly[9] that emphasis for research on CO_2-induced climatic effects should be on the transient response over the next fifty years.

The problem of estimating the transient climatic response also has a bearing on the selection of potential 'precursor indicators' of a CO_2 warming. Many of these suggested indicators tend to be regional in extent, such as the sea ice changes examined by Kukla and Gavin. This is significant because it has recently become apparent that different regions will probably respond at different rates to the continuous CO_2 build-up. For example, a simulation performed with a detailed coupled atmosphere/ocean model published recently by Bryan *et al.*[19] shows sea surface temperatures in near-polar latitudes responding relatively slowly to a stepfunction CO_2 increase compared with the global mean response. Thus, for the purpose of highlighting the most promising regional precursor indicators it is questionable whether one should put much confidence in regional climatic perturbations derived from steady-state simulations in which a CO_2 increase is held fixed[20]. A better way of identifying regional climatic changes with potentially good signal-to-noise ratios would be to search for these in the results of detailed time-dependent simulations performed with a coupled atmosphere/ocean model using realistic geography and plausible CO_2 increase scenarios[10].

In summary, then, the recent sea ice observations of Kukla and Gavin and the model versus observed surface temperature trend comparisons of the GISS group are at least consistent with consensus modellers' expectations for a climatic signal from increasing 'greenhouse' gases. We believe, however, that the statistical significance of these results is simply too small and the number of unverified modelling assumptions too large to allow one to proclaim 'detection'. But if Lacis *et al.* are right, then *this* decade, not the often cited year 2000, is when a clear warming signal is due. Verification of model predictions by the real atmosphere, of course, takes time; the recent results strongly suggest that the time is closer at hand than previously believed.

Evolution of photosynthetic pathways in flowering plants

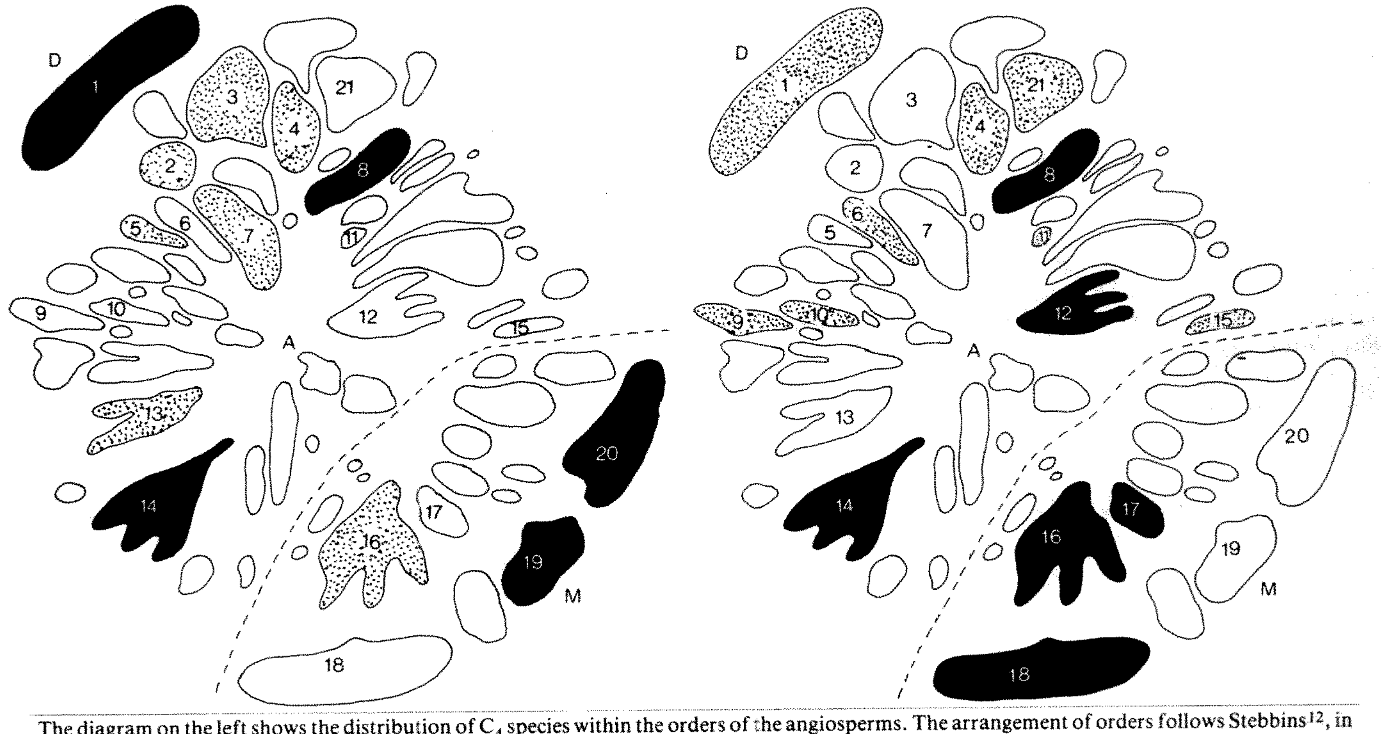
from Peter D. Moore

THE metabolic and anatomical characteristics of plants that possess either Crassulacean Acid Metabolism (CAM) or the C_4 photosynthetic pathway have long interested physiologists and have even begun to stir the imagination of ecologists[1], but relatively few people have applied themselves to the problems associated with the evolution of these mechanisms, beyond the cataloguing of their taxonomic distribution. Briefly, both CAM and C_4 plants have a 4-carbon atom molecule (oxaloacetate) as the first product of photosynthetic carbon fixation, though in the former this process occurs only in the dark. Both have low carbon dioxide compensation points (the CO_2 concentration below which a plant takes up less CO_2 by photosynthesis than it gives out by respiration), are insensitive to atmospheric oxygen concentration and lack photorespiration, by which glycollate is formed and subsequently degraded, thus releasing carbon dioxide. CAM and C_4 plants differ both structurally and ecologically: whereas C_4 plants have the so-called 'Kranz' (literally 'garland') anatomy with modified vascular bundle sheath cells to which the Calvin–Benson cycle carbon fixation system is spatially limited, CAM plants lack Kranz anatomy and the products of carbon fixation are not moved to specialized sites before liberation and fixation. Both types of photosynthesis are characteristically more frequent in hot, often (though not necessarily for CAM) arid regions, where the stomatal control possible with these modifications may be one of their greatest strategic advantages.

Wide-ranging surveys of the plant kingdom by physiologists and anatomists have resulted in a very considerable list of species in which the CAM and C_4 strategies have been found. Most are flowering plants, but at least one gymnosperm[2] and two pteridophytes[3] are reported to be CAM plants. The figure displays the taxonomic distribution of recorded CAM and C_4 species of flowering plants in a form that makes clear the presumed evolutionary development of the two systems. Two major points emerge: first, both CAM and the C_4 mechanism are widespread in the plant kingdom; yet, second, neither is found in what are considered to be the most primitive orders, such as the Magnoliales, Laurales and Ranunculales (that is, those orders close to the supposed 'ancestral complex' (A), within which the angiosperms originated). Perhaps the most primitive orders in which the pathways are found are the Sapindales (with C_4 representatives) and the Rosales (with CAM members). These observations lead to two logical conclusions: that the C_3 system is primitive in the angiosperms[4,5] and that both CAM and C_4 have originated independently and on many occasions during the evolution of flowering plants[6].

The polyphyletic origin of both mechanisms leads one to suppose that the genetic modifications involved in the adoption of either strategy are relatively small; indeed, the major enzymes required are already available in C_3 plants. One obvious way of investigating further this aspect of the subject is to seek and study plants which are intermediate between, say, C_3 and C_4 in character, either in wild populations of plants or as a result of breeding experiments in the laboratory. Rathnam[7] has now collated the information derived from such studies, but finds that natural hybridization has been recorded in only four genera of plants. The laboratory crossing of C_3 and C_4 plants, particularly the work of Björkman with *Atriplex*, has not produced a simple picture, even though individuals with intermediate characters have resulted. Rathnam concludes that the likelihood of introducing the C_4 mechanism to C_3 plants by genetic manipulation is not strong.

Peter D. Moore is a Senior Lecturer in the Department of Plant Sciences, University of London King's College, 68 Half Moon Lane, London SE24 9JF.



The diagram on the left shows the distribution of C_4 species within the orders of the angiosperms. The arrangement of orders follows Stebbins[12], in which they are shown to radiate from a proposed ancestral complex 'A'. Stippled orders contain fewer than 30 species with C_4 characteristics, shaded orders contain more than 30 species. Kranz anatomy is taken here to be an adequate criterion for C_4 designation, which may be questionable[9]. D, dicotyledons; M, monocotyledons. On the right is the distribution of CAM species among the angiosperms. Symbols as above. The data given in both diagrams are derived from refs 13–16. The numbered orders of flowering plants contain C_4 or CAM species: 1, Asterales; 2, Polemoniales; 3, Scrophulariales; 4, Gentianales; 5, Polygalales; 6, Geraniales; 7, Sapindales; 8, Euphorbiales; 9, Passiflorales; 10, Violales; 11, Rhamnales; 12, Rosales; 13, Capparales; 14, Caryophyllales; 15, Piperales; 16, Liliales; 17, Bromeliales; 18, Orchidales; 19, Cyperales; 20, Poales (Graminea); 21, Lamiales.

0028-0836/82/080647-02$01.00

Perhaps the most satisfying result to emerge from these studies is Rathnam's own work on the millet grass genus ***Panicum*** and in particular *P. milioides*[8]. This plant has a higher than expected phosphoenolpyruvate (PEP) carboxylase activity and an increased affinity for CO_2, which suggest C_4 tendencies. It has Kranz anatomy, an intermediate CO_2 compensation point of 16 μl l^{-1} (40–60 for C_3 and 0–5 for C_4) and is less sensitive to O_2 inhibition of apparent photosynthesis than a C_3 species, but more so than a C_4 species. Rathnam proposes that both photosynthetic pathways are operative within the leaf mesophyll of *P. milioides*, the C_3 system being unconfined and not limited to the bundle sheath cells as in the typical C_4 plant. Although the development of the C_4 pathway is incomplete, it would still provide the plant with the selective advantage of being able to concentrate CO_2 at the bundle sheath and thereby reduce photorespiration. On the basis of these findings, Rathnam proposes that the evolutionary development of Kranz anatomy precedes the metabolic modifications involved in the C_4 pathway, in which case Kranz anatomy is not a reliable indication of the C_4 capacity of a plant[9].

Fortunately, a resolution of these difficulties is suggested by this hypothesis recently put forward by Cockburn[10], who focuses on the mode of operation of the stomatal guard cell. Here, malate (one of the 4-carbon atom molecules involved in both CAM and C_4 metabolism) is known to play an important part and to accumulate in the guard cell during its opening[11]. The malate is fixed from CO_2 using PEP carboxylase, the precise method found in both CAM and C_3 plants. According to Cockburn, "all the essentials of CAM are represented in stomatal guard cell metabolism". Becoming a CAM plant *sensu stricto* simply involves the expression of these characteristics not only in the stomatal guard cells, but in other cells as well. The development of true C_4 metabolism would therefore appear to be a somewhat more complex series of modifications involving the development of Kranz anatomy and the use of malate as a mobile carbon resource.

The polyphyletic origin of both CAM and C_4 is thus easy to explain. The question that remains is which came first, the vascular sheath garland, or the extension of the guard cell malate system? The answer will probably depend on where one looks for it. ☐

Dynein in the spindle?

from Jeremy Hyams

MITOSIS typically involves two distinct phases of chromosome separation: the movement of chromosomes to the spindle poles (usually referred to as anaphase A) followed by the separation of the poles due to spindle elongation (anaphase B). Although the mechanisms of mitosis remain unknown, the most attractive models envisage that force for chromosome movement is generated by an active sliding displacement between spindle microtubules coupled to controlled changes in their lengths[1,2]. Motility based on sliding is now well established for ciliary and flagellar beating, another form of movement involving microtubules. In this case, the active component is the ATPase protein dynein which reversibly interconnects the nine outer doublet microtubules of the ciliary or flagellar axoneme[3]. Crucial to establishing the role of dynein was the demonstration that demembranated sea urchin sperm flagella would resume normal beating movements when supplied with exogenous ATP[4].

The development of a similar, simple *in vitro* model for studying spindle function has, however, proved to be a far less tractable problem. Spindles are notoriously labile and, in general, may be isolated only in the presence of stabilizing agents, which, by definition, alter the characteristics of the organelle. The best alternative has been to use whole cells made permeable to added reagents by treatment with detergent. Most studies of this type have used a cultured cell line derived from the rat kangaroo called PtK_1. If extracted at the start of anaphase, PtK_1 chromosomes continue to move in an apparently normal fashion as long as the lysis solution contains ATP[5]. More recent studies of the permeabilized cell model have shown that anaphase A and B are physiologically distinct. Whilst the basis of anaphase A remains uncertain, ionic conditions required to maintain anaphase B closely parallel those which support flagellar beating. Chromosome separation is specific for ATP as an added nucleotide, is inhibited by non-hydrolysable ATP analogues and sulphydryl poisons and reversibly arrested by vanadate, a potent inhibitor of dynein ATPase activity[6,7].

Jeremy Hyams is in the Department of Botany and Microbiology, University College London, Gower Street, London WC1E 6BT.

In this issue of *Nature* (p.700) Cande reports further evidence for the dynein-like nature of the anaphase B chromosome motor, on the basis of its sensitivity to erythro-9-[3-(2-hydroxynonyl)]adenine (EHNA) which, like vanadate, specifically inhibits flagellar beating and dynein ATPase activity. This physiological evidence for the involvement of dynein in mitosis is supported by the identification in isolated sea urchin spindles of an ATPase which has a subunit molecular weight and ionic and nucleotide characteristics closely resembling flagellar dynein[8]. Although there have been suggestions based on immunological cross-reactivity that the same molecule is involved in both forms of motility[9], the likelihood is that, if the spindle dynein really does exist, it is distinct from its flagellar counterpart.

The organization of microtubules in the two situations is, for a start, quite different. In the axoneme, dynein molecules form cross-bridges between microtubules which all arise from the basal body and hence are parallel in their orientation. In the spindle, on the other hand, interaction is between microtubules originating from opposite poles and so having opposed polarities[10]. Mutants of the green alga *Chlamydomonas* in which the flagella lack the paired dynein arms divide normally[11]. Likewise human patients in which these structures are missing due to genetic defects suffer only from symptoms associated with ciliary paralysis and are otherwise normal[12]. More directly, however, antiserum raised against dynein from mammalian sperm failed to recognize the corresponding proteins in either cytoplasmic extracts or spindles of mammalian cells[13].

At this point the reader might be forgiven for concluding that a unified, and, better still, experimentally testable view of mitosis is at last starting to emerge. Other evidence, however, suggests that the situation is just as uncertain as ever. Particularly fascinating is a recent report from Aist and Berns[14] involving a more primitive organism, the fungus *Fusarium solani*. These workers used a laser microbeam to sever the region of the spindle between the retreating chromosomes. Surprisingly, chromosome separation in these nuclei did not cease but rather proceeded three times faster than in the undamaged controls. By contrast,

0028-0836/82/080648-02$01.00

irradiation of the cytoplasm adjacent to one of the spindle poles caused the chromosomes to move more slowly. Far from supporting a model in which active sliding between microtubules drives chromosome movement, these data are consistent with the spindle acting as a mechanical governor, maintaining a counterforce which resists the pull of some, as yet unidentified, extranuclear component.

It would be quite wrong to conclude that either of the two diametrically opposed views of spindle function presented here is incorrect. On the contrary, mitosis may well involve several distinct mechanisms which are expressed to different degrees in different organisms[15]. The new probes of dynein activity such as vanadate and EHNA may well prove valuable in assessing the contribution of sliding in different cell types. Indeed their value may extend way beyond the world of mitosis. In this issue of *Nature* (p.701), Beckerle and Porter further report that both reagents inhibit particle transport along microtubules in fish chromatophores. It may well be that dynein will be shown to be as ubiquitous a feature of microtubule-based motility systems as myosin is of actin-based ones.

Intracellular membrane traffic

from M.J. Geisow

GEORGE PALADE (Yale University), in opening the 92nd Ciba Foundation Symposium* on membrane recycling, reminded participants of a fundamental problem of cell economics. To grow, cells must maintain fluid membranes at ambient temperature. This requirement is purchased at the expense of high molecular diffusion rates (1–60 μm min^{-1}) which, unless controlled, would lead to randomization of membrane components. When it is realized that animal cells contain up to 10 distinct membranes with characteristic proteins and lipids and that extensive transport occurs between them (the macrophage recycles its 780μm^2 of membrane in 30 min), the full nature of the problem can be appreciated. Nature's

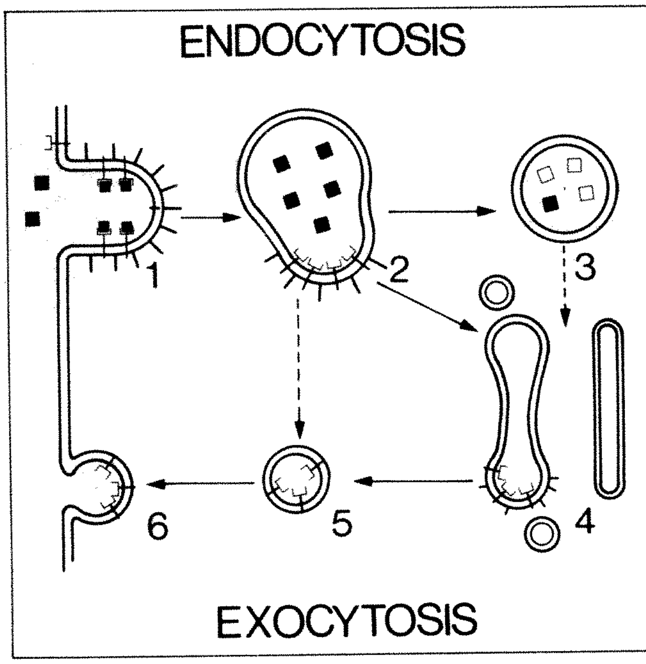
Nature's general solution appears to have been the development of membrane components which can self-assemble to form micro-domains. Within such domains, lateral diffusion rates are very much less than in bulk membrane. Well known examples are the specialized intercellular junctions and clathrin-coated pits. It was from the basis of this generalization, that cells can maintain anisotropic membranes, that the symposium considered how transport between occurs and by what routes.

Cells constitutively internalize their plasma membranes by endocytosis. Two routes of entry of membrane — through coated pits and uncoated invaginations — lead to coat-free, often irregular vesicular bodies in the peripheral cytoplasm of the cell. To designate this poorly characterized compartment, the terms endosome or pre-lysosome have been used, although in the specific case of receptor-mediated uptake initially occurring in coated pits, Ira Pastan and co-workers (NIH) coined the word 'receptosome'[1]. It is the ultimate fate of the endosome to fuse with a lysosome.

Clathrin-coated pits are probably micro-domains specializing in membrane protein selection. Mark Bretscher (University of Cambridge) showed some time ago that certain cell surface antigens, including Thy-1, are excluded from coated pits[2]. Surface receptors, by contrast, are sometimes present at relatively high surface density in coated pits. Clustering of receptors for low-density lipoprotein[3], α_2-macroglobulin[4] and galactose receptor[5] does not even require the presence of specific ligands and can be explained only by a relatively high affinity of pit for receptor protein. Unfortunately, the basis of this interaction is unknown, because structural analysis of coated membrane has not yet probed the organization within the lipid region under the clathrin cytoskeleton.

Immediately after uptake, receptor and ligand are present in coated vesicles, but within 1–5 min they are in uncoated endosomes. The intermediate coated vesicle, in cultured cells at least, must be a very transient transport element. One good reason for the short lifetime of the coat *in vivo* may be the need for partial or complete uncoating before fusion of the underlying membrane with another organelle. At the Ciba Symposium, James Rothman (Stanford University) described a timely uncoating activity in cytosol, which requires ATP.

Recent work has permitted closer biochemical definition of endosomes. They are not like classical secondary lysosomes, since cytochemistry demonstrates the absence of acid hydrolases. Nevertheless, endosomes may have relatively acidic contents. Spectroscopic studies[6,7] point to rapid acidification of endocytosed ligands. A clever confirmation of the low *p*H in the endosome has followed the observation that the fusion of Semliki Forest virions with lipid bilayers only occurs at or below *p*H 6.0. Viral infection *in vivo* necessitates the fusion of enveloped viruses, taken up via coated pits, with the endosome membrane. Ari Helenius (Yale University) has now shown that this fusion is prevented by weak bases such as amantadine which increase endosome *p*H (ref.8). Cells can be 'rescued' from irreversible infection only by supplying



Suggested sequence of intracellular receptor movements. Ligands (■) bind to receptors (┬) and are internalised through coated pits (1), where they are transferred to smooth-membraned structures (endosome, receptorsome 2.) Conditions within this compartment lead to ligand dissociation allowing receptors and ligands to follow different routes. The latter enter secondary lysosomes (3). Receptors may be conveyed to the Golgi (4) or a secretory vesicle (5) and return to the cell surface (not necessarily the same surface in epithelial cells) by exocytosis (6).

The existence of transport vesicles (not illustrated) which shuttle between these organelles is inferred. The nature of these and the topography of the receptors is unknown.

M.J. Geisow is in the Biophysics Division at the National Institute for Medical Research, The Ridgeway, Mill Hill, London NW7 1AA.

*The Ciba Symposium on 'Membrane Recycling' was held in London on 19–21 January 1982.

0028-0836/82/080649-02$01.00

the weak base within 4 min of warming cells with adherent virus to 37°C.

The low *p*H of endosomes may bring about dissociation of ligand and receptor protein. In experiments reported by Anne Hubbard (Johns Hopkins University), liver galactose receptor–ligand complexes are endocytosed at 16°C, a temperature at which endosome–lysosome fusion is impaired[5]. However, ligands still dissociate from receptors and the latter return to the cell surface, despite the absence of ligand degradation. It may be that these endosomes represent the elusive sites of receptor recovery — an acid wash through which regular 'preening' of the cell surface can be achieved.

The fate of the ligands and soluble content of endosomes is clearer — they are transferred to secondary lysosomes and degraded, which for them is a one-way trip. Exceptionally, certain receptors, for epidermal growth factor or the Fc portion of immunoglobulin, also enter lysosomes. Whether this is because their affinity for ligands is unaffected by the low *p*H in the endosome or because of intrinsic differences in the molecular structures of such receptors, remains an open question.

Equally enigmatic is the direction taken by the receptors which do recycle following the dissociation of their ligands or their normal recovery during membrane recycling in the absence of a specific ligand. Specific labels are lost at this stage and anti-receptor immunocytochemistry can only demonstrate the total cellular distribution, not the pathways of recycling. However, the endocytosis of cationized ferritin (CF), a positively charged, electron-dense marker which binds tightly and non-specifically to membranes, has provided some indirect evidence of how receptors recycle.

Kinetic studies of the endocytosis of CF by pituitary cells and lymphocytes made over a number of years by Marilyn Farquhar[9,10] show that after its appearance in endosomes, CF enters the trans elements of the Golgi stacks. After 30 min, CF appears on the inner membrane of secretion granules and therefore on the exocytotic leg of its journey through the cell. Autoradiography of iodinated surface membrane proteins suggests essentially the same route — although slow techniques such as conventional fixation and electron microscopy provide images which reflect rate-determining stages in the flux through a cell, so this picture may be incomplete.

In at least one case there is good evidence that CF follows the same route as receptors. Richard Rodewald (University of Virginia) has described transcytosis or diacytosis (passage through a cell) of maternal IgG across the intestinal epithelium of new-born rats[11]. The immunoglobulin is bound by Fc receptors at the gut lumen and is discharged into the neonatal circulation. Efficient segregation of IgG–Fc receptor complexes from soluble markers occurs in the endosomes near the sites of absorption (coated pits). The integrity of the receptor–ligand complex may be favoured in this case by low *p*H, since the neutral *p*H of the neonatal blood affects dissociation of the complex when it appears at the basolateral cell surface. CF accompanies the ligand through the same pathway and is exocytosed, still in membrane-bound form, at the sites of IgG release.

Considerable advances have been made in this popular area of cell biology, to which an increasingly 'molecular' approach is being applied. There remain, of course, major problems. We still need to account for the fast recycling times of cell membrane (seconds in the neuromuscular junction) and certain receptors (a minute or less for low-density lipoprotein receptor). Do these membrane components have time to follow the pathways described above? The relationship between endocytosis of membrane components through coated and uncoated regions is also unclear. Most telling of all, however, is the degree of our ignorance of the nature of the signals which direct this extensive traffic of receptor proteins and orchestrate the flow of cellular membrane. To understand these, we need techniques which allow us to observe the membranes from within the cell itself. □

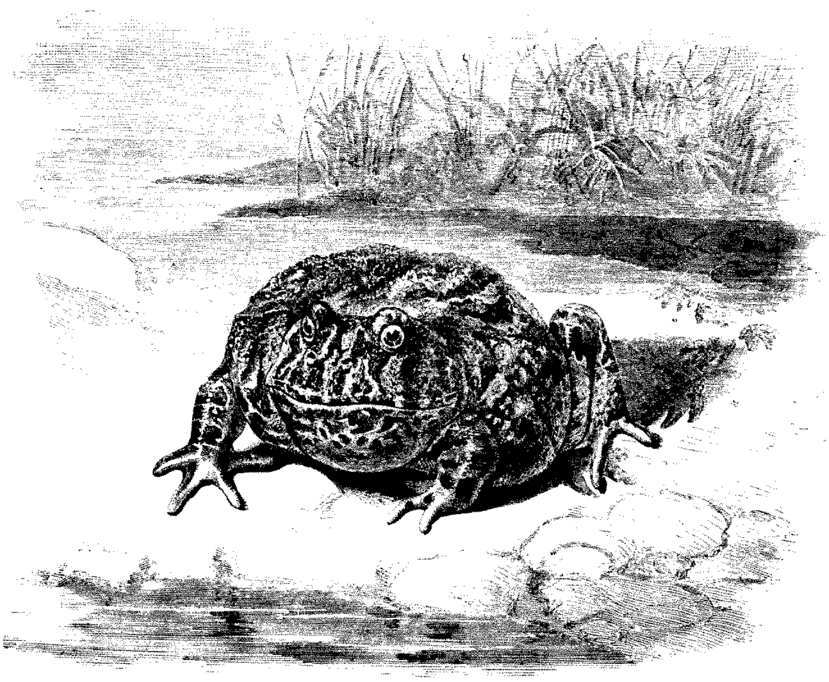
100 years ago

Amongst the batrachians exhibited at the Zoological Society are several species of gigantic size when compared with their puny representatives in this country, such as the Agua Toad (*Bufo agua*) of Brazil and the Ocellated Bladder-Frog (*Cystignathus ocellatus*) of Buenos Ayres. But by far the most remarkable of these forms in the series is the Adorned Ceratophrys, or "Esquerzo" of the natives of the Argentine Republic — a large toad of brilliant colours and extraordinary form, of which a figure (Fig 16) is now given, taken from a water-colour sketch prepared by Mr Ernest Griset.

The Esquerzo was discovered by Mr Darwin during the celebrated voyage of H.M.S. *Beagle*, and first described by the late Prof. Bell in the "Zoology of the Voyage of the *Beagle*." This monster inhabits the pampas of Buenos Ayres, and is said to feed chiefly on its smaller brethren of the same class. Mr Ernest William White, F.Z.S., to whom the Society is indebted for one of the two specimens now in the Gardens, specially mentions it in his lately-published "Cameos from the Silver-Land" as one of the characteristic forms of the grassy plains of the Argentine Republic. "In the damp grass," he says, may often be perceived the leering eyes and mottled black and green body of the huge Esquerzo (*Ceratophrys ornata*), whose gaping mouth crammed with the body of an unfortunate sapo (toad), and surmounted by threatening horns, inspires terror. This said Esquerzo bears an awfully spiteful character, and is credited with the deaths of many children.



THE ESQUERZO, OR BARKING TOAD

REVIEW ARTICLE

Very large ground-based telescopes for optical and IR astronomy

J. R. P. Angel

Steward Observatory, University of Arizona, Tucson, Arizona 85721, USA

Optical and IR astronomers are taking a hard look at their ground-based facilities and devising new ways of making more economic, bigger and better telescopes. Features of instruments of the 15-m class are likely to include servo control to compensate for atmospheric wavefront errors as well as structural deformation, large honeycomb mirror blanks and mirror surfaces produced by economical techniques developed for aspherics.

WHILE detectors and instrumentation have improved enormously during the past 50 yr, the size of the largest optical telescopes has not increased significantly. Detectors have now reached close to the fundamental noise limit set by photon statistics and techniques have been developed to observe simultaneously many objects in the telescope's field of view. Further progress in many problems of astrophysics now requires an order of magnitude increase in light grasp.

The main purpose of increasing telescope aperture is to reach fainter objects and to improve accuracy of measurement. The quantum nature of light means that to measure intensity, spectrum or polarization to a certain accuracy, even with ideal detectors and optics, requires the collection of a certain minimum amount of energy. For other types of measurements in which detector noise is dominant, the rate of collecting energy is an additional factor, and gives an added advantage to the large telescope. Given that on average only a few hours each day meet all the requirements for observing, and that the largest telescopes must serve a broad community of observers, it is not practical to integrate for more than around 20 h in a season the light from even an object of exceptional importance. For a given collecting aperture this sets a limit to faintness or accuracy.

The qualitative advantages to larger apertures arise from the improved limit to angular resolution set by diffraction. At long IR wavelengths, where image quality is limited by diffraction, high spatial resolution is achieved directly. At shorter wavelengths various interferometric techniques allow the recovery of information on spatial structure at the diffraction limit. This is <10 m arc s in visible light for the telescopes I now consider.

In the US a programme has been started to develop the critical technology for a national telescope with a collecting area equivalent to 15 m diameter. Closely linked projects for smaller telescopes for California and Texas are under way. Meanwhile, in Arizona, the Multiple Mirror Telescope (MMT), a joint research facility of the University of Arizona and the Smithsonian Institution, is a working prototype of many aspects of the new technology. Most ideas for very large telescopes involve multiple primary mirror elements, and the MMT, the first of this type, has six mirrors of 1.8 m diameter all bringing light to a common focus (Fig. 1).

Why ground-based?

The Earth's atmosphere limits the value of ground-based telescopes in various ways. It is completely opaque to wavelengths below 0.3 μm while the IR spectrum is broken up by molecular absorption bands, being completely blocked over the range 40–300 μm. Background radiation from air scattering of sunlight and moonlight, and from thermal emission in the IR interferes with the observation of faint objects. Refractive index changes caused by thermal gradients in the air prevent one achieving diffraction limited images at shorter wavelengths, and the uncertainty of weather means one cannot be sure of any particular observing period.

These limitations are removed for telescopes above the atmosphere. The Space Telescope, scheduled for launch in 1985, will overcome many of these problems. However, its aperture of 2.4 m diameter has only 1/40 the area of a 15-m telescope, while its cost is an order of magnitude larger. Although technology may become so advanced that one could afford very large telescopes to realize the potential of space, our present needs for huge light grasp can only be met by building on the ground.

In fact, many of the observations that need large aperture can be done efficiently through the atmosphere provided that the design, siting and scheduling of the telescope are optimized. Spectroscopy will be the major application for a very large telescope. Provided the atmospheric background is kept to the minimum, the dominant noise source for this work will often be photon shot noise of the signal itself, or detector noise in IR spectroscopy—these noise sources are not reduced by going to space.

Image quality

The factor that most strongly drives cost is the need for excellent image quality. This is required not so much to resolve detail in extended objects but to minimize the background underlying faint unresolved objects. A giant light bucket with indifferent images would be of relatively little value. If, for example, the spectrograph entrance aperture has to be increased in diameter to capture the light of a degraded image, then the increased background may overwhelm the signal. For the faintest objects doubling the telescope diameter is of no advantage if the image diameter is also doubled.

Our intention of achieving good images is likely to have far-reaching consequences for telescope design. Recent experiments and studies demonstrate that some degree of active correction for atmospheric distortion is generally possible, with potentially very large gains for giant telescopes in the IR. If the means to implement such corrections are an integral part of the telescope design, then they may also be used to correct for slight distortion of the optics which would be intolerable otherwise. Large cost savings may be possible if a correction system were to relax the normal tolerance for accuracy, rigidity and stability, especially if the optics are extremely large.

The distortion at the atmosphere can be thought of in terms of the corrugation of a wavefront that was perfectly plane when incident at the top of the atmosphere. It has ripples and waves on all scales, which can be modelled by random turbulence[1]. (Note, however, that turbulence inside the telescope housing has only small scales, and causes separate problems discussed separately below.) The random wavefront deviation δ in micrometres between points separated by d across the wave is given by

$$\delta(\mu) \simeq (d/d_0)^{5/6} \qquad (1)$$

0028–0836/82/080651—07$01.00

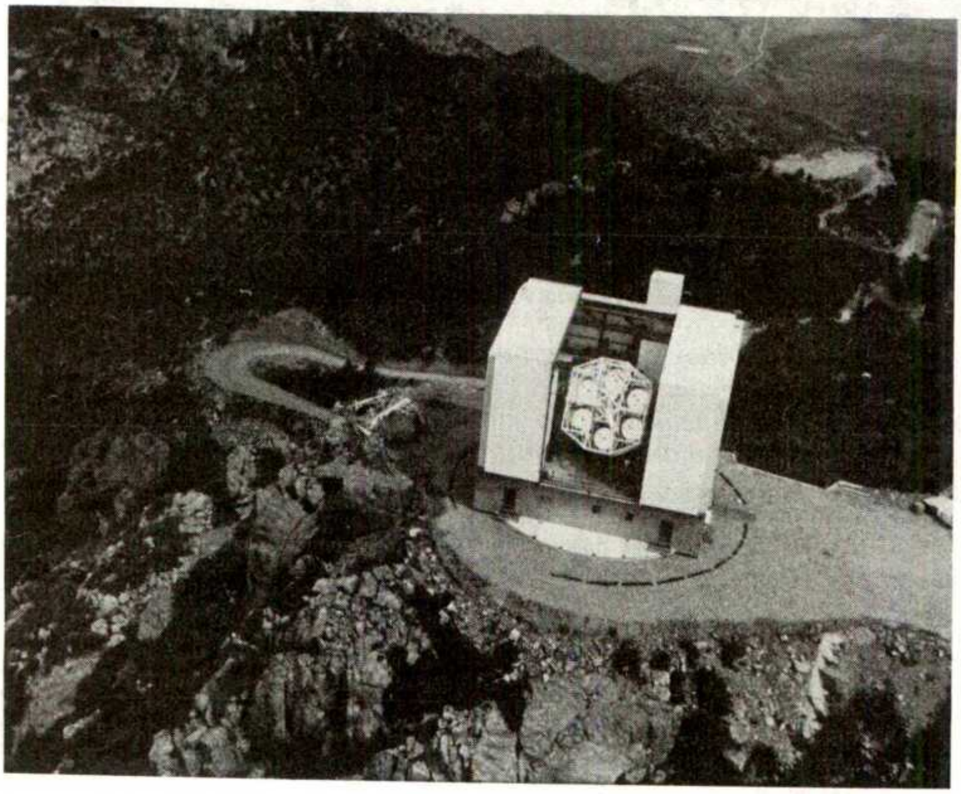

Fig. 1 An aerial view of the Multiple Mirror Telescope in Arizona. The location on top of a sharp, high peak, gives favourable conditions for sharp images. The MMT is jointly owned and operated by the University of Arizona and the Smithsonian Institution.

where d_0 is a measure of the seeing quality and in good conditions may be as large as several metres. The corrugations move at about the wind speed, so that large-amplitude deviations over a scale of 10 m change on a time scale of 1 s, while ripples on a scale of 10 cm vary 100 times faster.

If a true diffraction limited image is to be obtained at any given wavelength, then the deviations across the telescope aperture must not exceed about $\lambda/10$ (see ref. 2). For visible light, the task of correcting the wavefront of a large telescope to this tolerance is extremely difficult. The length scale of ripples with amplitude $>\lambda/10$ is 10–20 cm at best and the time scale is short. Compensation has to be made at an optical surface that can mimic all these rapidly changing small-scale ripples. Considerable progress in making such 'rubber' mirrors has been made by Hardy[3]. Apart from engineering difficulties, however, a fundamental limitation to achieving complete correction of the visible light wavefront is that of deriving the information needed to make the correction. This requires that the source being observed should be bright, or that there should be a bright source no more than a few arc seconds away whose wavefront, similarly distorted, can be used to derive corrections.

Although full correction of the wavefront is generally not possible, correction of the errors on a scale of metres is. Faint field stars within a couple of arc minutes of a target are adequate to provide the necessary much reduced amount of information. From equation (1) we see that the wavefront tilts δ/d are almost as big at large scales as at small, varying only as $d^{-1/5}$, so significant improvement of visible image quality can be expected. Woolf[4] has analysed in detail the improvements that can be made in various conditions: typically, 20–30% reduction in image size can be expected in visible light[4,55]. The better the seeing, the greater the improvement to be made.

In the IR, there is dramatic potential for high quality imaging with large telescopes. At 10 μm, for example, the small-scale ripples that do most damage to visible images are below the $\lambda/10$ threshold, and are not noticed. The seeing disk, resulting only from large-scale waves, will be only a little more than half that of visible light. Woolf has pointed out, though, that if the large-scale errors can be measured and continually corrected with the aid of a nearby visible star, fully diffraction limited performance at 10 μm is achieved in reasonably good seeing conditions. For a filled aperture of 15 m diameter the FWHM of the Airy disk is 0.16 arc s. Because almost every source of interest at 10 μm is fainter than sky background, the advantage of operating a large telescope at this high resolution is enormous.

Thermal control

The frequency of occurrence of different degrees of atmospheric turbulence and hence wavefront distortion has been measured with small, low level, test telescopes by Walker[5]. The results show little difference between the good test sites. From these data and balloon observations of turbulence by Barletti *et al.*[6],

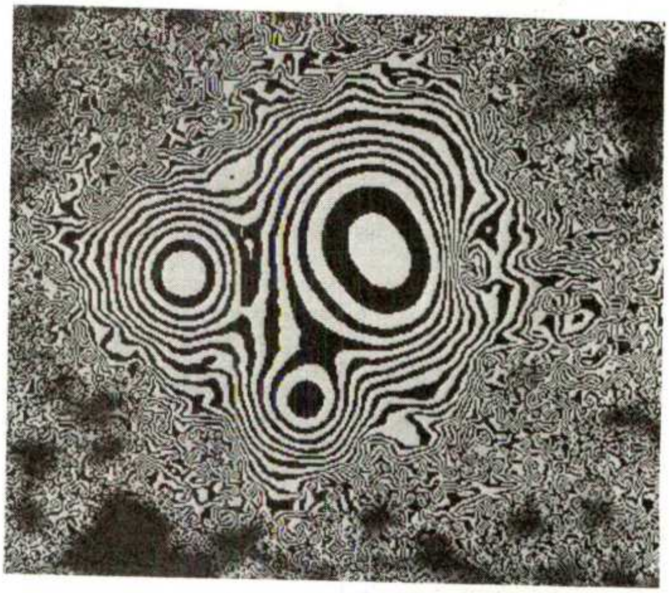

Fig. 2 An example of high resolution imaging from the ground, the QSO PG1115+08. It shows multiple components because of gravitational bending of light rays by an intervening galaxy. The two unresolved round images, separated by 2 arc s, have FWHM of 0.6 arc s. The brightest, elongated image is shown by speckle interferometry to be a double with 0.5 arc s separation[54]. This figure, courtesy of E. K. Hege, was made by Doug Tody at Kitt Peak National Observatory using the IPPS facility with contours space logarithmically by factors of two.

Woolf[7] has derived probability distributions for long exposure (time averaged) image size. He finds the diameter containing half the energy of a point source should be 0.7 arc s at the 50th percentile, 0.3 arc s at the 10th percentile.

The images that are actually recorded at most large telescopes are rarely as good as this, mostly because of thermal disturbance of the air near the telescope and enclosure. The increased size and thermal inertia of a giant telescope means we must be especially careful to understand and control these local effects. Adiabatic effects of turbulence on refractive index are not significant at normal wind speeds, but heating and cooling by convection and radiation are. The sensitivity to heat can be appreciated when we realize that light passing through a single bubble of air with a temperature difference of only 1 °C from its surroundings is spread into a cone of 0.5 arc s diameter. Turbulent thermal boundary layers can cause acute problems.

Local thermal gradients are potentially worse at high desert sites where diurnal changes of air temperature are large, and where radiation cooling at night is strong. The effects of an observatory building on image quality stem both from heat sources within the building and from failure of external surfaces to accommodate the changes in the ambient temperature. In the MMT building, exposed surfaces were of low thermal mass and were backed by good insulation, and the telescope chamber was small and well ventilated[8]. Beckers[9] reports a series of measurements at the MMT of temperature made with thermometers and a 10-μm TV camera, and of internal seeing measured with laser beams in the dome. The use of insulation and surfaces with low emissivity at 10 μm on the telescope and mount as well as the building, means that very good thermal equilibrium with the ambient air is achieved.

The one part of any telescope that cannot be insulated is the mirror. Seeing generated by mirrors has been studied by Lowne[10], who finds experimentally a seeing disk of 0.5 T arc s for a mirror temperature T °C hotter than ambient. Conventional large solid mirrors have time constants of many hours, and so are generally likely to be out of equilibrium by at least 1 °C from the changing night-time air, even if refrigeration is used during the day to set some anticipated mean operating temperature. Mirror seeing will thus frequently spoil potential sub-arc second seeing, unless the thermal time constant is kept to an hour or less. This goal can be achieved using metal mirrors or glass with faceplates no more than a few centimetres thick and air circulated behind. The fact that the MMT has thin-faced honeycomb mirrors may account in part for its frequently excellent seeing, despite substantial diurnal temperature variation at its high site. The image shown in Fig. 2 of the 'triple' QSO, having high resolution of 0.6 arc s, was obtained with one of the MMT honeycomb mirrors, with correction every 1 s for low frequency image motion caused by large scale wavefront tilts[11].

Ideas for very large telescopes

Traditionally telescopes have a single primary mirror made from a rigid massive disk of glass. Mirror supports for optical telescopes are based on the principle that perfect support against gravitational distortion of an elastic solid at any orientation is given by floating it in a liquid of the same density. Mirror cells arrange for the gravity balancing force to be distributed over the mirror back and sides, simulating flotation as far as possible. Thermal distortion of modern mirrors is effectively eliminated through the use of very low expansion materials having coefficient of $<10^{-7}$ per °C. Stiffness is such that the mirror figure is not significantly disturbed by wind in the telescope enclosure.

Mirrors of 4-m diameter are probably the limiting size for an economical telescope using these principles. Considerable increase should be practical if lightweight (thin or honeycomb) blanks are used together with some active compensation for mirror deformation and resultant wavefront distortion. Lewis[12] finds that on site manufacturing of a 10-m blank of 20 cm thickness out of fused silica or ultra low expansion (ULE) glass is practical. Studies of stiffness and designs for supports of thin meniscus mirrors of ULE or Zerodur in the 7–10 m range have been made by Epps *et al.*[13], Mack[14] and Pearson[15]. Pyrex honeycomb mirrors in this size range that would be considerably stiffer and potentially less expensive are under development[16,17]. Flotation support alone of large thin mirrors is unlikely to yield a surface precision much better than 1 arc s, particularly when one considers that wind forces in reasonable size domes will be large. However, with the aid of servo controls, as we have considered above for wavefront correction, slight errors in figure may not be a serious drawback.

The goal of a 15-m diameter primary aperture, which I adopt as representative of a very large telescope, is probably too large to be handled practically if made from a single piece of glass. Certainly the technology would have to be proved in smaller sizes before one could consider seriously such an approach. I thus consider designs that involve several or many separate mirror sections. For nearly all optical observations other than interferometry these separate elements could be in the form of separate telescopes, with data from separate instruments added to yield all the signal-to-noise advantage of the full aperture. Disney[18] has pointed out the advantages of such an array, in which fairly high spectroscopic resolution can be obtained with silicon CCD detectors without reaching the detector noise limit. Heterodyne IR interferometry would be possible with such an array[1], but direct interferometry and those IR observations which need all the light at a single focus[19] are almost impossible to achieve if the telescopes are on fixed separate mounts[20].

The most obvious route to a single focus is to figure all the elements as parts of a single parabolic surface. These must be mounted in a supporting structure as stiff as possible, and a scheme must be devised to manipulate the segments (or smaller elements reflecting images of the segments) to maintain correct orientation and phase. Such an approach has been studied by astronomers at the University of California. Nelson[21,22] and his collaborators are developing methods to prepare separately and bring together 25 off-axis hexagonal elements, to make an approximately hexagonal parabolic surface 10 m across. Angel *et al.*[23] have considered a design of six identical circular off-axis mirrors, each 6-m in diameter.

The MMT[24] takes an intermediate approach between separate telescopes and a segmented single reflecting surface. The experience of this working prototype has led to proposals[4] for much larger versions. A design for a 15-m telescope now being studied in some detail incorporates four 7.5-m honeycomb glass primaries co-aligned in a single telescope mount. Many optical observations would be done with relatively small instruments at the four separate foci but, as in the MMT, auxiliary mirrors would be arranged to bring the light to a combined and phase focus when needed. In this concept structural deformation and wavefront errors could be compensated in the small secondary optics or the primary mirrors.

Both the single-surface concept and the multiple telescope concept have the potential of yielding a telescope which can optimize images yet is versatile enough to undertake optical, thermal IR or interferometric observations. These approaches are being considered for the United States national 15-m telescope by a consortium of the Universities of Arizona, California and Texas with Kitt Peak National Observatory. This effort is concentrating on the key areas of technology that need development, bearing in mind a target cost of around $100 million.

Other concepts for very large telescopes which have received considerable attention are generally less versatile, but may have an important part to play for special tasks. Designs based on the Arecibo radio telescope with a fixed spherical bowl and moving secondary optics[25–28], solve the problems of gravitation distortion of a moving primary surface. Spherical segments of the surface could be produced inexpensively and spherical figure can be maintained easily against thermal deformation by laser metrology from the centre of curvature. However, performance

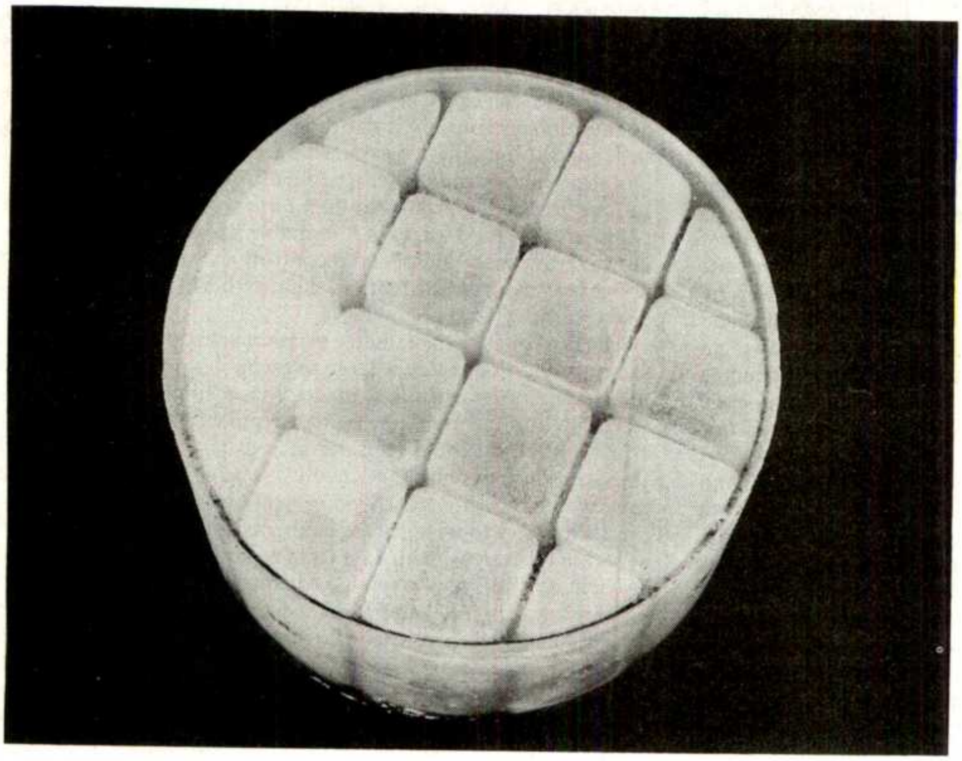

Fig. 3 A honeycomb–faceplate sandwich mirror blank cast from borosilicate glass as a single piece[14]: it is 60 cm in diameter and 35 cm thick, with ribs 6 mm thick on 15-cm squares.

in the thermal IR would be poor because of varying background as the detector tracks across different parts of the sphere. Also sky coverage is limited and it is difficult to correct spherical abberation over a large field of view. Furthermore, it would be expensive to raise such a telescope above the turbulent thermal boundary of the ground. A valuable application for this type of telescope would be for multiple object spectroscopy, in which a small corrector would be used for each point object under study, and many such correctors would be tracked at once across a limited spherical focal surface of some 20–30° (ref. 29). Multiple object spectroscopy is, of course, an important application of any of the giant telescopes discussed here.

A large telescope configuration that might become very important, with more experience with interferometry, has been suggested by Low[30]. Several telescopes would move on circular tracks, so as to remain in a line perpendicular to the object under study. If individual lightweight and stabilized telescopes of 5 m or more in diameter could be moved in this way, then the array would also be a good general purpose telescope. A fundamental question is the image quality that can be achieved in telescopes close to flat ground with no domes.

Making mirror elements

A central issue of any plan for a very large telescope must be a technique to fabricate the huge reflecting surface at acceptable cost and in a reasonable period of time. Without new ideas, mirror costs could take up most of the entire budget. If very low expansion materials are to be used then any structures other than solid sheets are probably ruled out because of very expensive fabrication costs. Costs for material alone are in the range \$50–100 kg^{-1}.

Borosilicate glass honeycomb is an attractive alternative for large mirror elements. The raw material is inexpensive and can be easily fabricated into complex structures by casting at relatively low temperatures. Figure distortion is a problem in solid borosilicate glass mirrors because temperature gradients persist for a long time, but will not be significant in a structure that can rapidly be made isothermal. The Palomar 5-m, the Lick 3-m and the KPNO 2.1-m mirrors are ribbed Pyrex structures with thickness of faceplate and ribs of ~10 cm. Thermal distortion of these mirrors is generally below the 1 arc s level[31]. At Steward Observatory we have undertaken to make large blanks consisting of 3-cm faceplates and still thinner wall honeycomb sandwiched between. These will be ventilated internally with air at ambient temperature, so equilibration will be rapid. A fundamental advantage is that mirror seeing, discussed earlier, will be eliminated. Two 60-cm test mirrors have been made from borosilicate glass: one has a slotted strut type of construction[32] and has been figured to a $\lambda/8$ r.m.s. sphere. The other, a similar honeycomb sandwich but made by a single casting in a complex mould, is shown in Fig. 3. Thermal relaxation and structural properties of both mirrors are being investigated by interferometry. Efforts are now directed towards casting in one piece

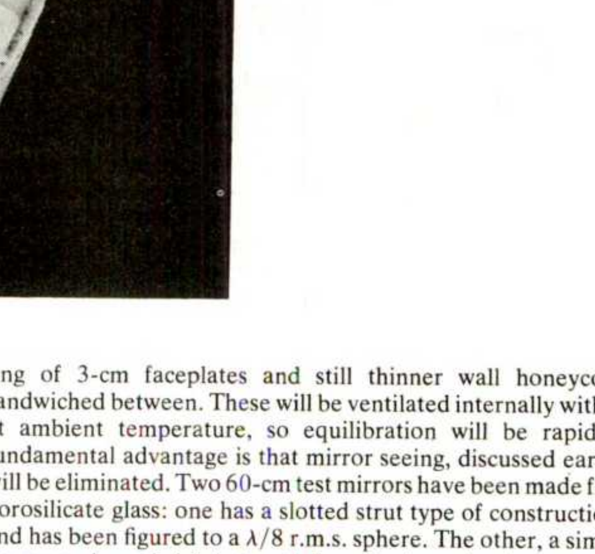

Fig. 4 Atmospheric-induced motion in one coordinate of two stars close to the North Pole separated by 50 arc s. Each data point gives the centre of gravity of an image integrated for 1/6 s. The r.m.s. fluctuation of the difference in positions is 0.11 arc s (ref. 41).

a honeycomb–faceplate sandwich mirror 1.8 m in diameter that will be figured as a parabola and tested alongside the fused silica mirrors in the MMT. We hope to work up to a 7.5-m blank over the next few years.

Ideas for reducing cost are needed in optical figuring. Traditional methods of grinding and polishing are time consuming and expensive for aspherics. One solution was devised by Schmidt, to make the aspheric corrector plates for his camera. A glass blank is polished spherical by conventional methods while being stressed in such a way that on release it takes up the required figure. Lemaitre[33] has demonstrated this method for making on-axis paraboids, making a diffraction limited $f/2$ parabola of 40 cm diameter. Nelson *et al.*[22] have extended the technique to make a precise off-axis parabola 35 cm in diameter, stressing the blank during manufacture with levers at the edge. The major effort of Kitt Peak National Observatory in the field of large telescopes is directed towards making matched off-axis elements 2m in diameter by the same method[34]. Precise tolerance in curvature ($\sim$1 in 10^5) is needed if a large parabola is to be made from separately figured segments. Another area of concern[35] is how these elements are to be made hexagonal, so they can be fitted together to make a nearly seamless surface of low thermal emission. Trimming a large thin circular mirror could disturb its figure as strain is relieved.

Traditional methods of figuring glass are based on the fact that two rigid blocks rubbed against each other with abrasive between will develop surfaces that are very accurately spherical. Machines to do the rubbing need not have any great precision, they only have to drag one piece across the other in a suitable pattern. A different approach is used in the production of optical surfaces by diamond turning of metal substrates. This is done with an extremely accurate lathe, and a single diamond tool of large radius advanced gradually so as to leave a mirror-like finish with only very shallow grooves. Optical elements up to a metre or so with surface accuracy of the order of micrometres have been produced by this method. Polishing can then give surfaces with better than a wave accuracy and remove the small-scale structure[36].

Unfortunately, metal substrates have not yet been demonstrated that can withstand the repeated temperature cycling of mountain top observatories without gradually losing their shape. Glass, while stable, cannot be finished like metals with a single diamond, but precision direct machining is possible with an abrasive diamond grinding wheel. This can again bring the surface to within a micrometre or so of the final figure, minimizing the work to be done in polishing. Large mirrors or segments would be turned on an air bearing about a vertical axis, and the tool moved across the surface as in Leighton's[37] method of making precision radio telescopes. Parks and Angel[38] have worked out a scheme to make mirror segments in which the grinding tool moves on an arm turned about an axis inclined to the vertical, yielding naturally a very close approximation to a parabola.

Electronic image stabilization

Despite the electronic sophistication available, large telescopes are being built which rely exclusively on massive rigid optics and supports to maintain image quality: only the MMT has used active control to replace force rigidity. The potential for achieving very large collecting areas by this technique at relatively low cost is enormous: the MMT has been built for about one-quarter the cost of its rigid equivalent.

There are various ways that active correction might be made. For single-mirror telescopes (or individual elements of a bigger telescope) we can alter the forces that support the primary, or leave it alone and devise a mechanism to distort the secondary or subsequent mirrors. For high frequency control, Hardy's scheme[3] uses piezo-electric actuators acting on the back of a thin mirror. Merkle *et al.* have demonstrated[39] an electrostatic force system. Magnetic actuators could be used for correction on a less rapid time scale.

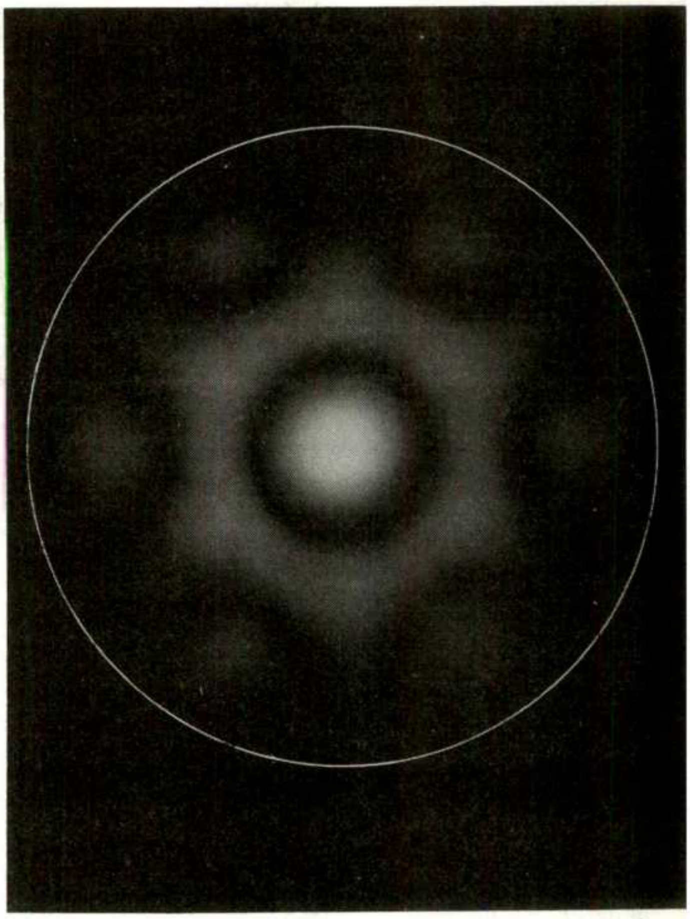

Fig. 5 The diffraction pattern computed by Meinel *et al.* for a phased circular array of six mirrors separated by 0.15% of their diameter. 40% of the total energy is within the first dark ring. The peaks in the continuous hexagonal ring reach 0.11 the intensity of the central peak, the six isolated peaks 0.06. The Airy pattern of one individual mirror, with a first dark ring of diameter shown by the white circle, has a resolution nearly four times poorer then that of the phased pattern.

To achieve a single focus in telescopes that have more than one collecting mirror we need to sense and correct the alignment of each mirror. In the MMT the tilt of individual secondary mirrors is controlled by micrometers driven by stepper motors, giving single steps of 0.05 arc s at the combined focus. Gabor[40] has demonstrated a ball screw actuator suitable for tilting 2-m primary elements with even higher angular precision.

How do we derive the information necessary to make corrections? Elastic deflections arising from differing orientation with respect to the gravitational field are repeatable, and tables of corrections necessary for their compensation can be stored in the control computer. There will remain unpredictable errors, such as wind forces, uncompensated thermal gradients in the structure, and friction in mirror supports, and in the MMT these residual effects amount to about 1 arc s in image motion[9] and a few tens of micrometres in pathlength error as the telescope is moved to different parts of the sky[30]. The residuals which might be achieved in a 15-m class instrument, probably not much worse than in the MMT, are comparable with the random wavefront error already present from atmospheric turbulence.

To realize fully the potential of active optics, one must determine how rays from a star illuminating different parts of the reflecting surface come together at the focus, and feed back corrections to the active elements. This will correct both the structural errors and the large-scale wavefront errors, if done with a frequency response of a few hertz. One method is by

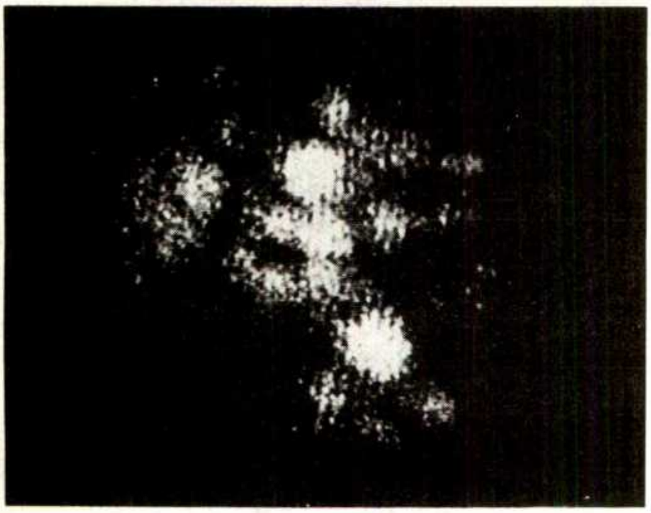

Fig. 6 Interference fringes spaced by 30 m arc s in the highly magnified image of an unresolved star. The image was formed by two of the 1.8-m mirrors of the MMT, with a centre-to-centre spacing of 5 m. (Courtesy of E. K. Hege and P. A. Strittmatter.)

automating the knife edge test: in its basic form the star image is focused on a sharp edge, such as a razor blade, and an auxiliary lens is used behind the edge to form an image of the primary mirror. A tilt of the wavefront in a particular region will then show as a bright or dark patch in the image. Hardy[41] has used a scheme in which an oscillating grating cuts across the star image, and the pupil is imaged on a bank of photomultipliers. Phases of the signals from each photomultiplier then give the tilt error of each part of the pupil. A variant of this idea is where the reference star is imaged on a sharp four-sided pyramid, and each reflected beam passes through a Fabry lens to image the pupil on one of the four sensitive imaging detectors[4]. A complete map across the pupil of tilt of the wavefront in both directions is obtained by intercomparison of the four pupil images. An alternative method that does not use a knife edge uses a lens placed after the combined focus to image the pupil on an array of tilted mirrors. Each mirror directs light from a part of the pupil to a field reimaging lens, and imaging detectors monitor the full field image from each pupil segment. Image locations relative to a reference dot in the combined focal plane then give the tilt of each pupil segment. In both these schemes the problem of maintaining co-alignment of a multiple element telescope reduces to the same problem addressed by offset guiders in today's single element telescopes. An automated system has to be reproduced for each section of the primary that will be independently corrected.

For the wavefront error correction to work, one must either use part of the light from the program star itself, or use a field star close enough for it to share the same large-scale wavefront errors. The angular separation α of shared motion is approximately d/h, where d is the scale of the wavefront error and h is the effective height of the wavefront disturbance. For $d = 2$ m and $h = 4$ km (ref. 42), α is about 2 arc min. Well correlated motion of two stars 50 arc s apart observed with a 1.8 m aperture in conditions of reasonably good seeing (1.2 arc s) is shown in Fig. 4 (ref. 43).

Because much of the work of a large telescope will be with faint objects giving no useful signal for electronic stabilization, the capability for continuous fine tuning of the image relies on finding a guide star within the field of common motion. Fortunately, the development of CCD detectors of excellent red sensitivity means that adequate signals can be obtained. Consider, for example, stars of R magnitude <16, which with a red filter would stand out clearly even in full moonlight. At the sparsest regions near the galactic poles these have a density of 382 per square degree[42], and will thus be found with 75% probability within a 2 arc min radius. The light from such a star collected by a 2-m element will give a signal of 8000 electrons s^{-1} in a CCD, adequate to implement the schemes outlined above with a frequency response of a few hertz.

When rapid wavefront tilt corrections are made to a telescope with continuous primary and secondary surfaces then instantaneous large-scale phase errors are also removed. As discussed earlier, this should allow diffraction-limited performance to be achieved in the IR. Even if the full collecting aperture is made from separate elements it should still be possible to maintain correct phasing from tilt measurement provided that the elements are close to each other, and that no steps are allowed to develop in the wavefront going from element to element. Relative phases between elements can be established by occasional observations of broad band interference in an unresolved reference source[30]. For a system of adjacent segments making a single surface, capacitive sensors such as those developed by Gabor[40] can be used to maintain accurately steps between adjacent mirrors.

The diffraction pattern of MMT type telescopes when multiple circular apertures are combined perfectly in phase has been explored elsewhere[25,45,46]. The intensity at the central maximum of the pattern depends only on the total collecting area; at this point all the radiation is added in phase no matter where it was collected. The width of the central peak depends on the diameter of the full array. An exact calculation of a typical diffraction pattern is shown in Fig. 5. This is for a circular array of six mirrors, separated by 0.15% of their diameter. Such a close array could potentially be maintained in phase from tilt sensing. The power of such a telescope for IR imaging is realized when we consider the potential resolution at 10 μm. Equation (1) shows that the phase errors over individual 6-m mirrors will get to $\lambda/10$ or less in good seeing. An MMT configuration of six such mirrors with active correction of phase differences between mirrors would give images close to the diffraction limit of Fig. 5, that is 0.11 arc s FWHM of the central peak, the same as for a filled aperture of 22-m diameter.

Although active wavefront correction to achieve directly diffraction limited images for visible light is not generally possible, various interferometric techniques can be used to study spatial structures at the diffraction limit. Very large single mount telescopes will allow resolution of ~5 m arc s at 0.5 μm. An example of interferometry between the full surface of two of the 1.8-m mirrors of the MMT is shown in Fig. 6. The centres of the mirrors are separated by 5 m, giving a fringe spacing of 30 m arc s at the observed wavelength of 0.75 μm. A specialized interferometric telescope array, such as Labeyrie is building, will give longer baseline and higher resolution than any single large telescope, but the latter will be able to reach considerably fainter objects[47].

Instrumentation and operation

We have focused on current ideas for making the large telescopes which, nevertheless, have excellent images; it is beyond our scope to review other characteristics, but we can indicate some of the challenges.

The sensitivity of present large telescopes in the wavelength range below 1 μm is being brought close to the theoretical maximum using silicon arrays. CCDs have near unit quantum efficiency and negligible noise for nearly all applications. We must also plan to use these detectors in very large telescopes: the challenge is to handle the inevitably large detector area. Because optics of present telescopes and spectrographs are close to the fastest practical speeds, increases in detector area proportional to the primary collecting area are inevitable. Detector areas from 10 to 1,000 cm^2 will be needed, depending on the number of spatial and/or spectral resolution elements to be resolved in a single exposure. Just as we will probably make large collecting areas from more than one piece of glass, we will probably need to make the detector from more than one piece of silicon. Many options exist for arranging detector chips in close mosaics, or in multiple smaller instruments. Some of the factors are discussed in ref. 18.

Another challenge is to maintain a sizeable field of view for a very large telescope. With good detectors there will be an important role for precise photometry and objective spectroscopy[48] of many thousands of objects at once in a wide field. With fibres automatically positioned in the focal plane and feeding the light along the slit of a spectrograph, dozens of objects can be observed over a wide field at once, with high spectral resolution if required[49,50]. If the primary focal ratio is made very fast to keep down tube length and dome size in a single-surface telescope, difficulties can arise in obtaining a wide field. However, two-element reflecting correctors offer a remarkable opportunity of obtaining a large corrected field with a fast primary. An optimized design[23] of the Baker–Paul type[51,52], explored in detail by ray tracing has an $f/1$ primary and an $f/2$ corrected focus. The achromatic images are no worse than 0.2 arc s over a 1° field.

The third challenge in a giant telescope is to maximize the operational efficiency. The best use is to match the type of observations to the conditions prevailing. Moonlight and twilight are obvious factors but there are also unpredictable changes in transparency, seeing, water vapour, wind and clouds. Ideally one needs several complementary instruments, ready for use with only a few minutes time lost for interchanging. Astronomers need not be present at the site for observations with standard equipment: they could be called to a local data terminal when their observations were to be made. Experiments in this type of operation have already begun at Kitt Peak National Observatory[53].

Multiple detectors, automated multiple object probes, automatic interchange of instruments, resident observing staff and communication with remotely located astronomers are expensive. When we consider, though, the capital investment in a 15-m class telescope, the costs of development, construction and operation of these instruments will not be disproportionate.

Conclusion

We are seeing the beginning of a new generation of large telescopes for optical astronomy, characterized by innovative methods of mirror fabrication and active feedback to maintain image quality. Large, rigid mirror substrates of honeycombed glass are being developed, along with techniques for inexpensive manufacture of precision aspheric surfaces. Advances in sensors and data processing now make it practical to measure continuously atmospheric distortion and make rapid corrections to the wavefront to improve image quality. Very large telescopes incorporating these mirrors and active control should work better and cost less than if built by conventional means. Remarkable advances over current levels of performance, beyond simply collecting more photons, now seem within reach. A 15-m telescope can potentially, with a modest degree of wavefront correction, give images at 10 μm approaching 0.1 arc s in diameter. This is comparable to the diffraction-limited resolution of the space telescope in visible light. Interferometry with the 15-m telescope at visible wavelengths will allow the exploration of structures in faint objects at 5 m arc s resolution, approaching the resolution achieved at radio wavelengths with interferometry over intercontinental baselines.

These unique advantages for higher spatial resolution argue that the first of the very large instruments should be a phasable design. However, when several very large telescopes are to be built it may be advantageous to design different complementary specialized types. For example, a very large telescope directed towards spectroscopy at shorter wavelengths might take the form of an array of independent smaller telescopes, or of a fixed spherical dish with tracking foci, and could be conveniently located on a lower mountain. Telescopes for thermal IR and submillimetre work need to be as high as possible for low water vapour and put a premium on the largest possible phased aperture. Again, for high resolution interferometry widely spaced large telescope elements are needed that move smoothly along the ground. Each type has a place.

This review has benefited from discussions with colleagues at the University of Arizona and the Smithsonian Institution. In particular, Nick Woolf inspired the discussion of atmospheric effects and has made many suggestions for improving the manuscript. I also thank Jacques Beckers and his staff at the MMT, for it is at this telescope that we are working out many of the basic new ideas common to proposed advanced telescopes. Work was supported by the NSF under grant AST 78-22714 and NASA NAGW-121.

Chain silicates, both naturally-occurring and synthetic, exhibit 'backbone repeat' patterns of corner-linked SiO_4 tetrahedra. The extent to which these repeats may be interpreted or predicted, as a function of the associated cation M^{2+} (in the general formula $MSiO_3$), is discussed, and the broader issues involved in the theoretical simulation of the structures of inorganic silicates are considered.

NATURALLY-occurring and synthetic silicates display an extensive range of structural types including isolated anions, chains, rings, sheets and various kinds of framework, all based on SiO_4^{4-} tetrahedra[1-3]. The diversity of structural types is exceptional, being matched only by the borates, where both trigonally and tetrahedrally bonded atoms may occur[4]. Even so, the total number of known silicate structures is substantially less than that theoretically predicted on simple topological arguments. Several attempts[5,6] have been made recently to rationalize and interrelate the structures of the silicates using largely qualitative solid-state, chemical principles. We have pursued a quantitative approach with the hope, ultimately, of predicting the behaviour of many different kinds of novel silicates. Such computations also offer an attractive method of assimilating new structural information brought to light[7-11] by real-space crystallography, using high-resolution electron microscopy (HREM). In particular, we have sought to interpret the structure composition relationships that have emerged from HREM studies of the so-called pyroxenoid silicates[12,13].

The pyroxenoids possess a general formula $MSiO_3$ ($M \equiv Ca^{2+}$, Fe^{2+}, Mn^{2+}, Mg^{2+} and so on). They display intriguing variability in their structural types and inter-relationships. The difference between individual members of this family manifests itself in the backbone repeat patterns of the single chain of corner-sharing SiO_4^{4-} tetrahedra.

Nature of the experimental facts

Figure 1 shows the various kinds of backbone repeat patterns characteristic of the diopside ($CaMg(SiO_3)_2$), wollastonite ($CaSiO_3$), rhodonite ($(Mn, Ca)SiO_3$) and pyroxmangite ($(Mn, Fe, Ca, Mg)SiO_3$) structures. In wollastonite, three SiO_4^{4-} tetrahedra constitute the unit (7.3 Å in length); in rhodonite, the five-unit repeat runs to 12.5 Å; whereas in pyroxmangite the seven-unit repeat is 17.4 Å. Diopside, with a two-unit repeat (5.2 Å), is an archetypal member of the pyroxene family of chain silicates: the other three are pyroxenoids.

X-ray studies of naturally-occurring and synthetic analogues of pyroxenoids are fraught with difficulties principally because of the occurrence of complicated intergrowths of various members of the pyroxenoid range of structures. Great headway can, however, be made[14-17] by real-space direct methods (HREM) as may be seen in Fig. 2. Although it is difficult to be sure that equilibrium states have been reached, certain preferences for given pyroxenoid structures can be noted for given cations (or stoichiometric ratio of cations). Thus, as the synthetic pyroxenoid of formula $Mn_3MgSi_4O_{12}$, emerges from the glassy state, the pyroxene structural type is first seen to predominate, with embryonic regions (a few unit cells in width) of various other pyroxenoids (Fig. 2*a*). Eventually (after prolonged annealing at 800 °C) a marked propensity for the pyroxmangite structural type prevails (Fig. 2*c*); but an intermediate stage (Fig. 2*b*) may be detected by HREM in which strips of wollastonite are inserted regularly to produce small regions of pyroxmangite.

Likewise the synthetic pyroxenoid of formula $MnFeSi_2O_6$ first displays some individual strips of nine-unit backbone repeats (that is the ferrosilite III structure which has a unit length of 22.7 Å) interspersed amongst pyroxmangite and rhodonite structural types (Fig. 3*a*). Gradually (Fig. 3*b*), five-unit repeats gain ascendancy, and a well-ordered rhodonite (five-unit repeat) ultimately prevails.

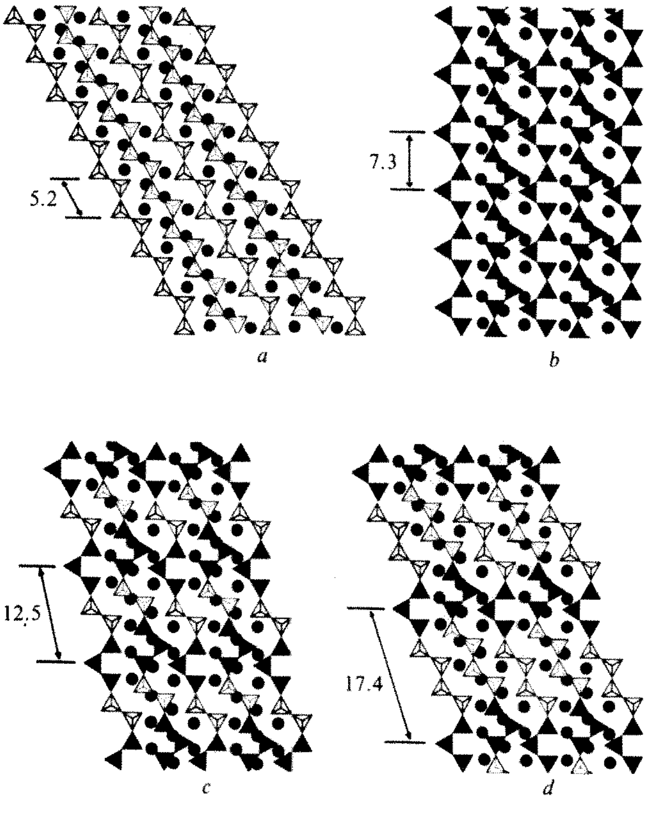

Fig. 1 Illustration of the pyroxenoid structures referred to in the text. *a*, Diopside (two unit repeat); *b*, wollastonite (three unit); *c*, rhodonite (five unit); *d*, pyroxmangite (seven unit).

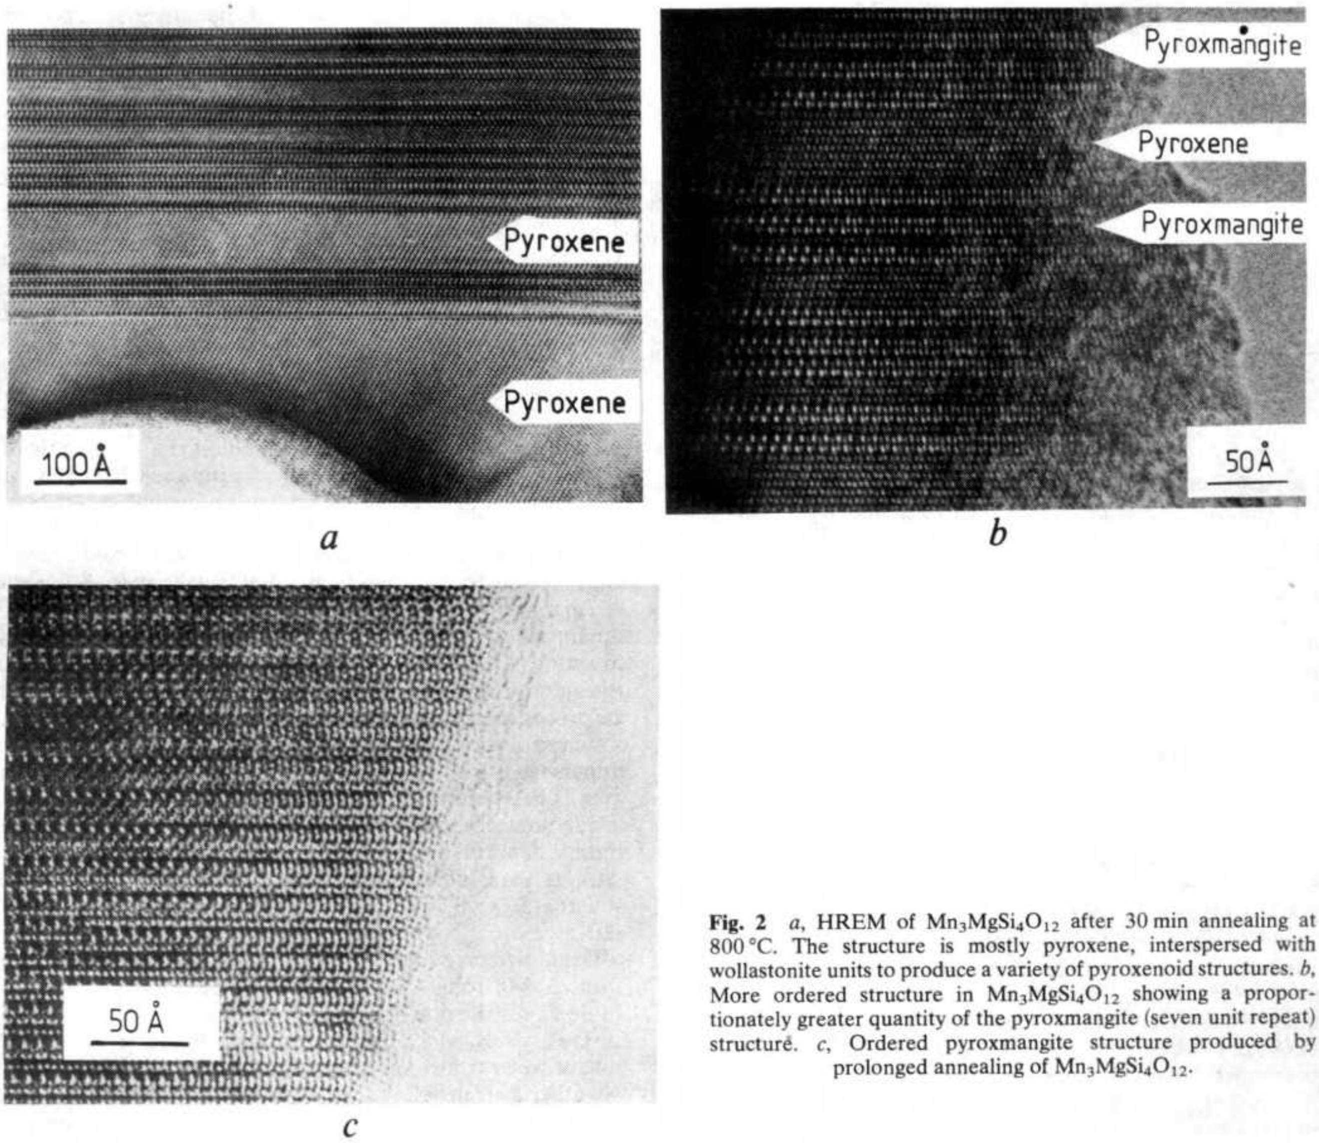

Fig. 2 *a*, HREM of $Mn_3MgSi_4O_{12}$ after 30 min annealing at 800 °C. The structure is mostly pyroxene, interspersed with wollastonite units to produce a variety of pyroxenoid structures. *b*, More ordered structure in $Mn_3MgSi_4O_{12}$ showing a proportionately greater quantity of the pyroxmangite (seven unit repeat) structure. *c*, Ordered pyroxmangite structure produced by prolonged annealing of $Mn_3MgSi_4O_{12}$.

One key question to which our simulation studies are addressed is which structural type is preferred for a particular cationic sublattice? A related question raises the issue of whether mixed cations (ordered or disordered?) can tilt preference from one structural type to another?

Knowing the success that procedures using pair potentials have achieved in interpreting the behaviour of molecular crystals, and organic solid-state chemistry[18–21], it seemed appropriate to evolve computationally more advanced procedures that could cope with the demanding set of circumstances associated with the silicates. Fortunately, the techniques developed by C.R.A.C. and Norgett[22–25], which have proved successful in the study of non-stoichiometry, extended defects and superionic conductivity, have considerable value in the present context and promise much more extensive interpretive scope in silicate chemistry. It has been shown[22–32] that simulation techniques can elucidate the nature of the complex defect aggregation modes in heavily defective systems such as $Fe_{1-x}O$ (ref. 26) and UO_{2+x} (ref. 27), and identify the factors that determine whether compositional variation is accommodated by extended rather than by point defects[28,29].

The simulation procedure

The methods are, at least conceptually, simple. A potential model is used to describe the interactions between the ions in the crystal; the energy of the crystal is then minimized with respect to all structural parameters. [The methods do not explicitly include the effects of thermal motion. However, this omission is unlikely to affect seriously the use of the methods for structural predictions.] In contrast to this conceptual simplicity the actual computational techniques are sophisticated. This relates first to the handling of the summation procedures, where we have developed procedures available in the PLUTO lattice simulation code[26] to evaluate the long-range electrostatic interactions. (Our methods are based on the Ewald transformation which replaces a slowly convergent summation in real space with a rapidly convergent reciprocal space sum). Second, efficient minimization methods are vital if we are to cope with large unit cells. Earlier work showed the advantages of Newton–Raphson procedures which result in rapid and stable convergence[30]. Special problems arise when the minimization procedure adjusts unit cell dimensions in addition to ion coordinates—an essential feature in the simulation of silicates.

Application of the techniques to silicates requires first, development of adequate potential models for these materials and second, adaptation of minimization procedures to handle the complex structural problems posed by these systems.

Potential models for the silicates

Successful simulation studies of transition metal and actinide oxides have been based on ionic model potentials with two-body, short range potentials described by a simple analytic function (generally of the Born–Mayer or Buckingham form). Although the ionic model is clearly an approximate description of the bonding in these oxides, there is growing evidence (which includes the success of the calculations) that the approximation

Table 1 Short-range parameters

* See refs 27, 39.
† See ref. 44.

is good for materials such as TiO_2 (ref. 31) NiO (ref. 32) and UO_2 (ref. 27). To what extent, however, has the model any validity when applied to quartz and to silicates? To answer this question we must first consider the meaning and implication of the term ionicity.

Following Cochran[33] we note that there are two distinct (although related) operational definitions of this concept. The first concerns the distribution of valence shell electron density, and although we have no definite evidence, use of this criterion would almost certainly suggest the inapplicability of the ionic model to silicates. The second criterion, which has much greater relevance to the present study, is in terms of interatomic forces and the response of the crystal to external perturbations (elastic or electrostatic) or internal structural modifications (such as the formation of defects or the introduction of impurity ions). In this context a solid is regarded as ionic if a description of the lattice based on ions can correctly predict (1) the lattice energetics of the solid, (2) its elastic and dielectric properties and (3) the formation energies of defects and structural response of the lattice to the introduction of disorder. This latter criterion is equally valid to, but distinct from, the former. It is essentially a definition in terms of forces rather than charge distribution. In the context of the debate on the extent of ionicity in solids, it is important that this distinction in the connotation of the term should be appreciated. We shall show below that the ionic model forms a reasonable basis for the simulation of silicates.

We have therefore developed ionic model potentials which are generally applicable to ring and chain silicates. Our procedure differs from that adopted in earlier studies of simpler inorganic oxides[27,29,32] where variable parameters in a general potential model were adjusted so as to give the best fit to experimental elastic and dielectric data. Such data are in general unavailable for minerals. However, the structures of complex low symmetry crystals are themselves a rich source of interatomic potentials, because, in such crystals a given type of interaction potential (say silicon···oxygen) is generally sampled over a wide range of separations. (This fact has already been successfully exploited[34], in developing a potential model for ZrO_2 from the low temperature, low symmetry structure.) We have, therefore, used the structural data available on a range of chain and ring silicates to develop our generalized potential model for these systems.

The precise procedure is as follows. First, we define the form of our potential model which has two main features: (1) the crystal is simulated by point entities of integral charge; and (2) short-range forces are included for the Si···O and O···O interactions (we discovered that inclusion of Si···Si interactions over short-range was not necessary in order to reproduce structural data on ring and chain silicates—a result which is apparently at variance with recent suggestions[5,35–38] concerning the dominance of these interactions in determining the structures of minerals.) The short-range forces are described by a potential of the form:

$$V(r) = A\, e^{-r}/\rho - Cr^{-6}$$

For the O···O interaction we took parameters (reported in Table 1*a*) which were derived from a quantum mechanical calculation of the interactions between two O^{2-} ions[27,39]. For the interaction between the metal cations and oxygen in the minerals studied, we used parameters obtained for the appropriate metal oxide. All metal–oxygen parameters used are listed in Table 1*a*. Interactions between metal and Si^{4+} ions were ignored, as these are negligible at the interatomic spacings in silicates. The parameters A, ρ and C for the Si···O interactions were taken as variables and were fitted to the structural data. This procedure involves adjusting the parameters until the forces acting on all atoms in the unit cell are zero, and the unit cell itself is in equilibrium with its observed dimensions. This is achieved by a second application of the PLUTO program, which, given a specified structure and potential, calculates both the forces acting on the individual atoms in the cell and forces of dilation or contraction acting on the unit cell as a whole. The program is linked with a least-squares routine which minimizes these forces with respect to the variable potential parameters. In practice, for relatively simple potentials of the type we have used, it is not possible to derive a fully strain-free potential. Thus, to check that our final fitted potential is in adequate agreement with the structural data, we allow the structure to equilibrate (that is achieve its minimum energy configuration by adjusting all structural parameters) using the potential. Our criterion for the acceptability of the fitted potential was that in the process of equilibration no atom should be displaced from its observed position by more than 0.25 Å. In general the discrepancies were much smaller than this figure (typical values were 0.1 Å). However, the neglect of thermal motions by our calculations when combined with the errors in the crystallographic data could lead to a discrepancy of this magnitude in an extreme case, although in general we would expect a good potential to give better agreement with high quality structural data.

The above procedure was applied to the six silicates listed in Table 2. We found that a single set of parameters listed in Table 1*b* for the potential could fit the observed structural data for the crystals, which include structures based on isolated SiO_4 units as well as rings and chains. On the basis of the second of the two criteria given below, the result supports the suitability of the ionic model for describing the bonding in these systems. The model yields correct structures for those crystals in which there is a considerable range of structural variation. The implication is that the forces in the silicate lattice are being described correctly, and this conclusion is supported by calculations of the lattice energies. Studies of silicates have been reported using ionic model potentials[40–43]; and the work of Jenkins *et al.*[41,42] has clearly demonstrated the accuracy of lattice energy calculations using these potentials We should note, however, that it is much more difficult to derive potentials which satisfactorily model structural data on more condensed silicate systems, that is layer and framework structures. Investigation of more sophisticated models for these systems is continuing.

We should emphasize the important differences between the approach adopted here and that used in earlier theoretical studies of mineral systems. First our approach is fully quantitative including representations of short range as well as

Table 2 Mineral structures used in calculating short-range parameters for silicon–oxygen interaction

electrostatic terms (which are the sole terms considered in several previous studies[41,43]). Second, structural data are used as a source of interatomic potentials. Third, energy minimization is used in predicting structural properties.

Further information on the viability of our parameterized potential will follow from the study of the structural effects of the variation of the divalent cation present in chain-structured systems. Before presenting the results of such calculations the problem of energy minimization must, however, be considered.

Minimization methods

Two points are of general importance to the simulation of complex crystal structures. The first concerns the adjustment of unit cell dimensions in such calculations. We found that, for example, on varying the nature of the divalent cation present in a pyroxenoid silicate it was inadequate merely to adjust the coordinates of the ions surrounding the divalent cation. It was also necessary to include dilation (or contraction) of the unit cell; and, moreover, the dilation must be allowed to be anisotropic. Indeed, failure to include anisotropic dilation may lead to qualitatively inconsistent results.

The second point concerns the question of the precise minimization techniques. Our general approach was to modify the unit cell dimensions followed by an iterative adjustment of the atomic coordinates until these are in equilibrium with respect to the new cell. Subsequent cycles then effect further variation of the cell dimension and the procedure continued until a structure is attained which is in equilibrium with respect to both unit cell parameters and atomic coordinates. Note that in adjusting unit cell dimensions it is very important to vary the angle between the axes of the cell as well as the lengths of the cell edges. Failure to include this feature will drastically reduce the efficiency of the minimizations. We should also note that the equilibrated cell

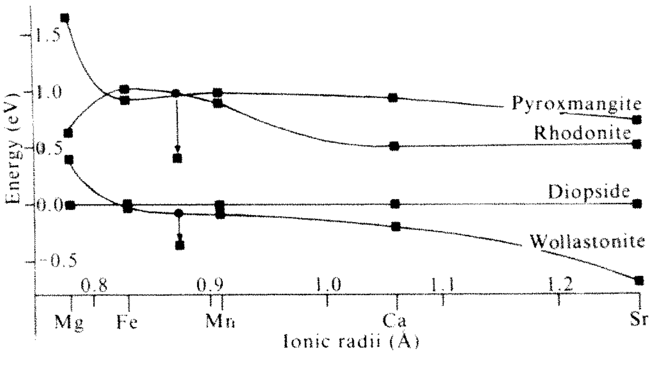

Fig. 4 Plot of energy (per mol SiO_3) relative to that of diopside as a function of radius of the cation M^{2+}. The arrow (↓) indicates stabilization arising from the mixed cation effect in Mn_3Mg; ●, result calculated for average cation radius.

dimensions were within 2% of observed values for all compounds for which crystallographic data are available.

Results and discussion

Calculations were performed on the four pyroxenoid structures, diopside, wollastonite, rhodonite and pyroxmangite. In each case the structures were investigated with the five cations Mg^{2+}, Ca^{2+}, Fe^{2+}, Mn^{2+}, and Sr^{2+}; a full minimization was performed both with respect to the unit cell dimensions and the ion coordinates. The results are summarized in Table 3, where we give the lattice energy of the equilibrated structures per Si atom; and Fig. 4 displays the calculated energies relative to that obtained for the diopside structure.

The following conclusions may be drawn from these calculations: (1) The pyroxmangite and rhodonite structures are never energetically favoured with respect to the diopside and wollastonite structures. (2) Pyroxmangite and rhodonite have very similar lattice energies especially for Fe^{2+} and Mn^{2+}. (3) The most energetically favoured structure is found to be wollastonite for all ions except Mg^{2+} for which diopside is preferred. The energetic preference for the wollastonite structure increases with the radius of the cation.

The first of the above conclusions does not apparently accord with the experimental data as stable rhodonite and pyroxmangite structures are observed. However, in most cases these are found with mixtures of divalent cations, for example, the structural pyroxenoid $Mn_3Mg(SiO_3)_4$, mentioned earlier, which has the pyroxmangite structure (Fig. 2). We investigated whether these structures could be stabilized by the presence of several, rather than one type of divalent cation. In practice, such calculations could be more conveniently performed on the rhodonite structure with 3/4 Mn^{2+} and 1/4 Mg^{2+} cations. (The Mg^{2+} cations were allocated to the smallest cation sites in the crystal.) The result was compared with that for a crystal in which all the divalent cations are the same with a potential taken as a weighted average of that for Mn···O and Mg···O interactions. The former was more stable, relative to the diopside structure, by 0.6 eV, than the latter, which gives an estimate of the magnitude of the 'mixed-cation' effect in this structure.

The wollastonite structures were stabilized by only 0.2 eV by this mixed cation effect, when this was calculated in an analogous fashion. Thus, although the relative stabilization of the rhodonite structure by the mixed cation distributed is insufficient in this particular case to render this structure more energetically favourable than wollastonite, the effect is clearly large and may be decisive in certain cases. One situation for which this appears to be so is $CaMg(SiO_3)_2$, which when an 'average' potential is used, is calculated to be more stable in the wollastonite structure, but when a proper mixed cation distribution is used is found to have greater stability (by 0.6 eV per Si) in the diopside structure as is observed experimentally.

Table 3 Calculated lattice energy of $MSiO_3$ per Si atom

Cation (M^{2+})	Structure Diopside (eV)	Wollastonite (eV)	Rhodonite (eV)	Pyroxmangite (eV)
Mg	163.534	163.133	162.909	161.888
Fe	159.673	159.682	158.582	158.754
Mn	159.204	159.285	158.311	158.232
Ca	158.424	158.622	157.921	157.496
Sr	156.081	156.725	155.564	155.359
Mn_3Mg	159.754	160.137	159.431	—
(Mn_3Mg) composite*	160.216	160.126	159.254	—
CaMg	161.139	160.683	160.130	—
(CaMg) composite*	160.958	160.778	159.926	—

Lattice energies are all calculated as negative quantities; the modulus is given in the table.

* (M_1 M_2) indicates a hypothetical ion with anionic radius equal to the mean of M_1 and M_2.

The results for $CaMg(SiO_3)_2$ and $CaSiO_3$ are thus most encouraging. Each is correctly predicted to have the structure that is observed experimentally. Moreover, the trend in the variation with ionic radius of the relative energies of the wollastonite and diopside structures is in accord with experiment. It remains an open question as to whether rhodonite and pyroxmangite structures are ever thermodynamically stable with respect to the wollastonite structure. On the basis of our results we suggest that pyroxenoids are metastable when they crystallize exclusively into either the rhodonite or pyroxmangite structures. Our computations also show that both structures may be stabilized if there is a mixed cation sublattice of the kind discussed above.

We shall show elsewhere that computations of the kind presented here also reveal much valuable information, pertaining to the behaviour of aluminosilicates such as zeolites. In particular the energetics associated with various possible Si, Al, ordering schemes[51,52] are assessed; and it transpires that the total energy of the aluminosilicates can be a sensitive function of cation position.

We thank the SRC for support and AERE Harwell for generous provision of computer time.

The nucleotide sequence of a complete cDNA copy of enkephalin precursor mRNA from human phaeochromocytoma is reported. The corresponding amino acid sequence shows that the precursor is 267 amino acids long and contains six interspersed Met-enkephalin sequences and one Leu-enkephalin sequence. Five of the seven enkephalins are flanked on both sides by pairs of basic amino acid residues. The precursor does not contain the sequences of the opioid peptides, dynorphin, α-neo-endorphin or β-endorphin.

A NUMBER of peptides have been isolated in the past 6 years that exhibit opioid activity. The simplest of these are methionine (Met)- and leucine (Leu)-enkephalin first identified in brain tissue in 1975 (ref. 1)[1]. The other opioid peptides are C-terminal extensions of either Leu-enkephalin or Met-enkephalin. For example, β-endorphin is a C-terminal extension of Met-enkephalin[2,3], and dynorphin[4] and α-neo-endorphin[5] are C-terminal extensions of Leu-enkephalin (Fig. 1).

Because of the structural similarities of these peptides it was postulated that β-endorphin is the precursor of Met-enkephalin and that dynorphin (or α-neo-endorphin) is the precursor of Leu-enkephalin. However, in the past 2 years it has become clear that the enkephalins are derived from a different gene product than β-endorphin, and that β-endorphin is synthesized from a protein, pro-opiomelanocortin (POMC), that contains sequences of adrenocorticotropic (ACTH) and melanocyte stimulating (MSH) hormones[6-8]. The source of the enkephalins has been elucidated recently by studying the biosynthesis of these peptides in bovine adrenal medulla[9,10]. Enkephalin peptides are abundant in adrenal medulla and can be released by neurotransmitters specific for that tissue. Several enkephalin-containing peptides have been purified from chromaffin granules of the bovine adrenal medulla and shown by sequence analysis to contain more than one enkephalin sequence[9,10]. These studies suggest that a precursor protein exists which contains multiple copies of the enkephalins and that the enkephalins can be released from this protein by digestion with trypsin-like enzymes[9,10].

Enkephalins are also abundant in human phaeochromocytoma, a tumour derived from the adrenal medulla. The RNA from this tumour contains a high level of enkephalin mRNA sequences as demonstrated by cell-free translation studies[11]. Therefore, we have used human phaeochromocytoma as a source of human proenkephalin mRNA for the preparation and cloning of human enkephalin cDNA.

We have previously shown that a synthetic oligodeoxynucleotide probe pool complementary to a mRNA sequence that codes for Met-enkephalin can be used to detect a proenkephalin mRNA species in bovine adrenal and human phaeochromocytoma by the Northern blot procedure[12]. These species of RNA are between 1,400 and 1,500 bases long. In the present study we have used the same probe to identify transformants containing recombinant plasmids with inserts of human proenkephalin cDNA. In this manner we have been able to derive the nucleotide sequence of DNA complementary to the entire human proenkephalin mRNA sequence.

Isolation of cDNA clones

Poly(A) RNA was isolated from human phaeochromocytoma tissue as previously described[12]. Northern blot analysis of this RNA, using an enkephalin pentadecamer pool ($5'\cdots\text{CAT}\genfrac{}{}{0pt}{}{\text{A}}{\text{G}}\text{AAGCCGCC}\genfrac{}{}{0pt}{}{\text{A}}{\text{G}}\text{TA}\cdots 3'$) containing two possible mismatches with the enkephalin-coding mRNA sequence, revealed that proenkephalin mRNA constitutes ~0.1% of the total poly(A) RNA from this tissue[12]. A four- to fivefold enrichment of enkephalin mRNA was achieved by density gradient sedimentation (Fig. 2). A clone bank of 15,000 tetracycline-resistant transformants was made from cDNA copies of the enriched enkephalin mRNA.

To screen and maintain the phaeochromocytoma clone bank, 7,000 transformants were picked and grown in 96-well microtitre plates. All cultures were transferred in ordered arrays to nitrocellulose for *in situ* hybridization with ^{32}P-labelled Met-enkephalin pentadecamer probe pool. Seventeen colonies hybridized strongly with the pool (Fig. 3). Plasmid DNA was isolated from the corresponding cultures and the size of cDNA inserts examined after endo *Pst*I cleavage by polyacrylamide gel electrophoresis. Most of the plasmids were found to contain both a 410 and a 600 base pair (bp) fragment. Several plasmids contained a third fragment of varying size. Two of the latter plasmids with the biggest inserts were selected for nucleotide sequencing together with the 600 and 410 bp fragments.

Sequencing strategy

To determine the nucleotide sequence of the cDNA inserts, recombinant plasmid DNA was cleaved with endo *Pst*I and the DNA fragments were cloned into the *Pst*I site of the bacteriophage vector M13mp7 RF-DNA. The single-stranded DNA prepared from recombinant phage served as a template for enzymatic sequencing reactions in the presence of chain terminators[13] using a synthetic oligomer as universal primer[14]. Figure 4 shows the entire nucleotide sequence of preproenkephalin mRNA as derived from sequencing the cDNA inserts of two separate clones. One insert contained the entire 5′ portion of the mRNA and ended ~20 nucleotides after the termination codon. The other had the entire 3′ end but did not

contain the region corresponding to the 5′-untranslated region of the mRNA and the portion coding for the signal peptide (leader or presequence).

Primary structure of enkephalin precursor mRNA

The mRNA coding for Met- and Leu-enkephalin is 1,350 nucleotides long (Fig. 4), close to the size of 1,400 nucleotides observed in Fig. 2*b*. The 5′-untranslated region is remarkable for being >200 nucleotides long. We do not know how many nucleotides are missing from the capped 5′ end of the mRNA. As artefacts can occur in the cDNA corresponding to the 5′ end of the mRNA, we cannot rule out that the actual mRNA sequence is different in this region[15]. The 5′ end features several stretches of homo-oligomeric pyrimidines, especially runs of UMP. The coding region starts with the first AUG and consists of 267 triplets with seven interspersed small repeat units corresponding to the enkephalin sequences. The 3′-untranslated region is 320 nucleotides long and is rich in UMP with several homo-oligomeric pyrimidine stretches towards the 5′ end. An AAUAAA sequence common to most mRNA species[16] is found 19 nucleotides before the poly(A) tail. It is curious that another such sequence occurs 20 nucleotides upstream. With both sequences represented in the chromosomal gene, it is possible that two populations of mRNA exist which contain either one or both sequences.

Primary structure of enkephalin precursor protein

The first 24 amino acids of the precursor protein have the characteristics of a leader sequence containing many hydrophobic amino acids, particularly Leu (Fig. 4). As Ala is the most common amino acid preceding the cleavage site of leader sequences[17], we tentatively conclude that the leader sequence ends after Ala 24, as indicated in Fig. 5, although Ala 20 is another possible termination site. The N-terminal one-third of the mature proenkephalin molecule does not contain any enkephalin sequences but consists of a 73 amino acid peptide (residues 25–97 in Fig. 4) containing all six Cys residues in the protein. A proper folding for efficient processing is probably ensured by the formation of disulphide bridges in this part of the precursor.

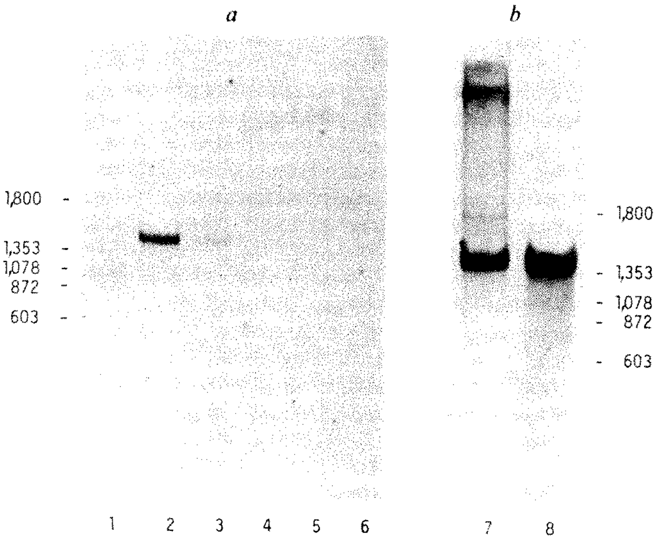

Fig. 2 Northern hybridization analysis of human phaeochromocytoma poly(A) RNA using enkephalin probes. *a*, Fifty µg of human phaeochromocytoma poly(A) RNA was fractionated on a 5–35% linear sucrose gradient at 4 °C for 16 h in a Beckman SW41 rotor at 35,000 r.p.m. Fractions from the gradient were precipitated and washed with EtOH and the pellets were resuspended in 10 µl of H_2O. Two µl aliquots from alternate fractions (0.8 µg) were denatured with glyoxal and electrophoresed in a 1.75% agarose gel for 3 h at 100 V. RNA was transferred from the gel to nitrocellulose[25]. The RNA blot was hybridized with 6×10^7 c.p.m. of ^{32}P-labelled pentadecamer probe pool (5×10^6 c.p.m. pmol^{-1}) in 5 ml of 4×SSC, 1× Denhardts, 0.1% SDS and 100 µg ml^{-1} yeast tRNA at 30 °C for 2 days. Hybridization and washing of blots was done as described previously[12]. Autoradiography was for 16 h at −70 °C using Dupont lightning plus intensifying screens. The top of the gradient is at the left hand side of the chart. *b*, Five µg of human phaeochromocytoma poly(A) RNA was hybridized with 1×10^7 c.p.m. pentadecamer probe pool (5×10^6 c.p.m. pmol^{-1}; lane 7) and 3×10^6 c.p.m. of nick translated pHPE 41 containing a nearly full-length proenkephalin cDNA insert (4×10^8 c.p.m. µg^{-1}; lane 8). The length scale (number of nucleotides) was constructed by running glyoxal-denatured DNA fragments of *Hae*III digests of phase ΦX174 RF-DNA and *Hin*dIII digests of phage λ DNA on adjacent lanes of the gel.

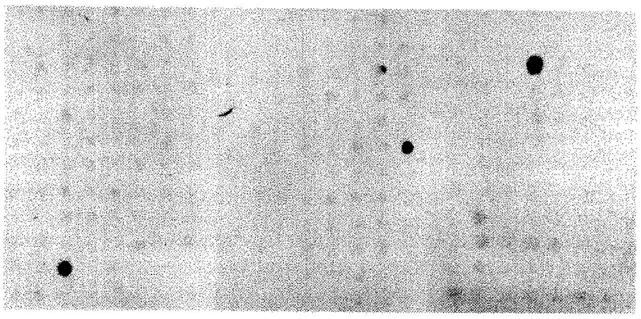

Fig. 3 *In situ* colony screening of a human phaeochromocytoma cDNA library using ^{32}P-labelled enkephalin pentadecamer pool. Sucrose gradient fractions containing enkephalin mRNA (Fig. 2, lane 2) were pooled and used to direct the synthesis of single-stranded cDNA using reverse transcriptase and oligo(dT) as primer. Double-stranded cDNA was prepared using the large fragment of DNA polymerase I (Boehringer Mannheim), and the hairpin loops were cleaved with S_1 nuclease (Miles). Double-stranded S_1-treated cDNA was fractionated on a 10% polyacrylamide gel and cDNA 600–2,000 bases long was eluted. Forty ng of size-fractionated cDNA were obtained from 2 µg of enriched poly(A) RNA. Poly(dC) homopolymeric extensions were added to the 3′ end using terminal transferase (PL Biochemicals). A clone bank of human phaeochromocytoma cDNA was prepared by annealing the poly(dC)-tailed cDNA to endo *Pst*I-cleaved plasmid pBR322 DNA tailed with dGMP[26], and the mixture used to transform competent *Escherichia coli* 294 cells. Approximately 15,000 tetracycline-resistant transformants were obtained from which <3% were ampicillin resistant. Seven thousand tetracycline-resistant colonies were picked and grown in 96-well microtitre plates. Colonies were transferred from the microtitre plates to nitrocellulose filters placed on 15 cm LB Petri plates containing 5 µg ml^{-1} tetracycline using a 96-prong stainless-steel stamp. Colonies were grown on the filters for 6 h at 37 °C after which the filters were transferred to Petri plates containing LB with 12.5 µg ml^{-1} chloramphenicol, and amplified overnight. Filters were lysed, neutralized and prepared for hybridization as described in ref. 27. Prehybridization of filters was for 6 h at 30 °C in 4× SSC, 2× Denhardts, 40 mM $NaPO_4$, *p*H 7.8, and 300 µg ml^{-1} heat-denatured herring sperm DNA. The pentadecamers were phosphorylated using T_4 polynucleotide kinase (New England Biolabs) and (γ-^{32}P]ATP (NEN) to a specific activity of 2×10^6 c.p.m. pmol^{-1}. ^{32}P-labelled probe pool was purified by chromotography on 10 ml Sephadex G-50 columns. Each 15×7 cm filter was hybridized in 2 ml of the above hybridization mixture at 30 °C for 20 h containing 4×10^6 c.p.m. pentadecamers. Filters were washed for 15 min, once at 25 °C and twice at 30 °C, in 4× SSC, 0.1% SDS, dried and exposed to X-ray film. Autoradiography was at −70 °C for 2 h using intensifier screens. Results are shown above for several filters containing positive signals.

It is tempting to speculate that the occurrence of multiple enkephalin sequences in the same molecule is due to duplication events of one small genetic unit in the distant past. If so, sequence changes dictated by diversified functional and processing requirements may have erased most of the supporting evidence, as can be seen by analysing the structure of the regions that separate the enkephalin units. The length of these 'spacer' regions ranges from 2 amino acids (between units 1 and 2) to 41 (between units 3 and 4). Four of these spacer regions contain highly hydrophilic sequences with several Glu and Asp residues in a row. The spacer peptide that separates Met-enkephalin unit 5 from Leu-enkephalin is missing this hydrophilic feature. It is interesting to note that this peptide (peptide E) is totally conserved in the bovine and human enkephalin precursors and is a more potent opioid agent than the enkephalins[10]. Perhaps processing of the hydrophobic spacer is less efficient than processing of the hydrophilic spacers. The hydrophobic spacer might ensure that peptide E is released intact from the precursor to serve as an opioid agent or another kind of regulator.

Fig. 4 Primary structure of human Met- and Leu-enkephalin in precursor mRNA and protein. Plasmid DNA was isolated by mini-screen procedure from 5 ml of overnight cultures and digested to completion with endo *Pst*I (New England Biolabs). Digested DNA was ligated to 10 ng of *Pst*I-cleaved M13mp7 RF-DNA in 20 µl containing 50 mM Tris-HCl, *p*H 8, 0.1 mM EDTA, 7 mM $MgCl_2$, 10 mM dithiothreitol, 500 µM rATP and 0.2 U of T_4 DNA ligase (New England Biolabs) for 1 h at room temperature. The mixture was used to transform competent *E. coli* JM103 cells and transformed cells were plated with top agar in the presence of isopropyl-tgio-β-D-galactoside and 5-bromo-4-chloro-3-indolyl-β-D-galactoside. After a 10 h incubation at 37 °C, colourless plaques were transferred to 1.5 ml 2× yeast-tryptone broth. Bacteria were sedimented from grown cultures by centrifugation and phage were precipitated from the supernatant with polyethylene glycol-6000 (3%) and NaCl (0.5 M). DNA was isolated by phenol–$CHCl_3$ extraction, precipitated with ethanol and redissolved in 10 µl of H_2O. DNA templates were sorted by single-lane tracking to avoid redundancy and non-productive sequencing generated by the empty phage DNA or poly(dG)-tailed sequences at the insertion site. For the final sequence determination, six templates were chosen which originated from two different cDNA clones. Sequencing reactions were done for 15 min at 25 °C in 4 µl of 10 mM Tris, *p*H 8, 0.1 mM EDTA, 7 mM $MgCl_2$ and 1 mM dithiothreitol containing about 100 ng of template DNA, 0.2 pmol of primer, 0.2 U *E. coli* DNA Polymerase I (Klenow fragment; Boehringer Mannheim), 5 µCi of [α-^{32}P]dCTP (Amersham, 400 Ci $mmol^{-1}$) and deoxy- and dideoxynucleoside triphosphates in the proper concentrations. A chase was performed for 15 min by adding 1 µl of a 2 mM solution of each of the deoxyribonucleoside triphosphates and reactions were stopped by adding 10 µl of a formamide–dye mixture. After heating the reaction mixtures to 100 °C for 3 min, 1 µl aliquots were electrophoresed on thin 40 cm long 5% polyacrylamide–8 M urea gels for 2–6 h at 25 mA. Gels were dried onto Whatman 3 mm paper and exposed to X-ray film overnight.

The molecular weight of the precursor calculated from the sequence in Fig. 4 is the same as that determined by Dandekar *et al.* for bovine adrenal medulla (31,000)[18] but much smaller than those reported for bovine adrenal medulla (50,000)[19], guinea pig striatum (92,000)[20] or human phaeochromocytoma (70,000–180,000)[11]. The estimates by Dandekar *et al.*[18] on the adrenal precursor and by Beaumont *et al.*[20] on the striatum precursor were made by SDS-polyacrylamide gel electrophoresis while the other estimate[11] was made by gel-filtration.

Special features of the human enkephalin precursor and possible cleavage products

Some of the special features of the enkephalin precursor are presented in Fig. 5. Five of the seven enkephalin moieties are flanked on both sides by pairs of basic amino acid residues (enkephalin moieties 1–3, 5 and 6, Figs 4 and 5), suggesting that they are cleaved out of the precursor by the combined action of a trypsin-like enzyme and a carboxypeptidase. Action of these

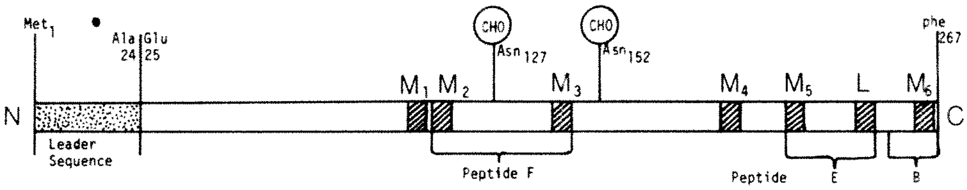

Fig. 5 Low-resolution model of enkephalin precursor showing the distribution of Met-enkephalin sequences (M_1, M_2, M_3 and so on) and Leu-enkephalin (L). The position of potential carbohydrate (CHO) attachment sites and the sequences corresponding to peptides F, E and B of bovine adrenal medulla[10] are depicted.

enzymes would also be expected to generate Met-enkephalin-Arg-Gly-Leu from enkephalin sequence 4 and Met-enkephalin-Arg-Phe from the carboxy-terminal region of the protein. Met-enkephalin-Arg-Phe has actually been observed in bovine adrenal medulla[9].

The biologically active domains of other prohormones, such as proinsulin[21] and POMC[22], are also flanked on both sides by pairs of basic amino acid residues, suggesting that similar trypsin-like enzymes are involved in processing of these prohormones. The amino acid sequence in Fig. 4 also reveals the existence of two potential glycosylation sites in the precursor at Asn 127 and Asn 152. The sequence Asn-X-Ser or Asn-X-Thr is required to attach carbohydrate to an Asn in a protein[23]. However, as not all Asn residues in such a sequence are glycosylated, it is not possible to predict whether the enkephalin precursor contains Asn-linked oligosaccharides[23].

Comparison of human pro-enkephalin- and bovine enkephalin-containing peptides

Kilpatrick *et al.*[10] have sequenced several large enkephalin-containing peptides isolated from chromaffin granules of bovine adrenal medulla. Comparison of the sequence of three of these peptides with the sequence of human proenkephalin shows that all three are contained within the human precursor. The sequence of bovine peptide B corresponds to amino acid residues 238–267 (the C terminus of the protein) of the human precursor with at least one amino acid substitution at residue 240 (a Pro in the bovine peptide for Ala in the human)[10]. The sequence of peptide E (a more potent opioid than the enkephalins)[10], which contains both a Met- and a Leu-enkephalin moiety, corresponds exactly to the sequence of residues 210–235 in the human enkephalin precursor. The sequence of peptide F (34 amino acids long) corresponds to the sequence of residues 107–140 in the human precursor with five amino acid substitutions. The amino acid substitutions in human peptide F are (human for bovine) in positions 120 (Met for Leu), 122 (Pro for Val), 129 (Ser for Gly), 131 (Leu for Val) and 133 (Ala for Gly). It is interesting that peptides E and F have pairs of basic amino acid residues flanking both sides of the enkephalin sequences they contain. As pairs of basic amino acid residues are potential tryptic cleavage sites, this finding suggests that peptides E and F are processing intermediates in the formation of enkephalins. Yet the high potency of peptide E as an opiate and the complete conservation of sequence between human and bovine peptides indicate that this peptide is an important opiate compound in itself.

Enkephalin-like immunoreactivity has been observed not only in several areas of the brain but also in sympathetic ganglia, nerve plexuses in the intestine and nerve fibres in adrenal medulla and phaeochromocytoma. It would be very interesting to know whether the same array of opioid peptides is produced in these tissues as in adrenal medulla. Tissue-specific use of enkephalin peptides could occur by differential processing of the precursor molecule or by selective expression of one or more of a family of enkephalin genes in different tissues. Isolation and characterization of enkephalin genes will be an important step in attempting to answer this question.

Close examination of the structure of the human enkephalin precursor reveals that it does not contain the sequence of any of the other opioid peptides, β-endorphin, dynorphin or α-neo-endorphin. Hence, at least three of the four types of opioid peptides are derived from different primary gene products.

The complete sequences of the precursors to β-endorphin (POMC) and enkephalins are now known. In both precursors there is repetition of a sequence that is flanked on both sides by pairs of basic amino acid residues. POMC has three copies of the MSH sequence[22] and the enkephalin precursor has seven copies of the enkephalin sequence. J. Kurjan and I. Herskowitz have recently discovered that α-factor, a peptide pheromone 13 amino acids long that promotes sexual union of yeast gametes, is synthesized from a precursor containing four copies of the peptide in an evenly spaced arrangement (personal communication). The α-factor sequences are flanked on only one side by a pair of basic amino acid residues indicating that the proteolytic processing of the precursor is different from that of proenkephalin and POMC.

Thus widely diverse organisms make use of the multivalent precursor for the synthesis of important regulatory peptides. In the case of POMC, peptides from different regions of the precursor (MSH, ACTH and endorphin) may act as agonists or antagonists in coordinating a behavioural response such as the response to stress[24]. The function of the multi-enkephalin precursor is less clear.

This work was supported by National Institutes of Health Grants AM-16879 and GM07759. We also thank R. Swanson for his support.

Note added in proof: While this paper was in press two papers appeared in the 21 January issue of *Nature* on the structure of the enkephalin precursor in bovine adrenal gland[28,29]. The distribution of enkephalin sequences in the human precursor is very similar to that in the bovine precursor.

Studies of X chromosome DNA methylation in normal human cells

Stanley F. Wolf & Barbara R. Migeon

Department of Pediatrics, The Johns Hopkins University School of Medicine, Baltimore, Maryland 21205, USA

Studies of methylation along 28 kilobases of X-chromosome DNA, assayed by Southern blot analysis using cloned X-chromosome-specific probes, indicates that X DNA methylation in normal human cells changes with replication, is not correlated with number of X chromosomes or transcriptional activity, and is less stable and more prevalent than when the human X is in the foreign environment of mouse–human hybrid cells. In contrast with observations of others in heteroploid cells, we observed no derepression of the inactive X in clonal populations of normal human fibroblasts treated with 5-azacytidine. This may reflect the differences in stability of the methylation of the human X in a foreign environment. Our observations preclude ubiquitous methylation differences as the molecular basis for X-chromosome inactivation.

DNA METHYLATION has frequently been proposed to be responsible for the regulation of developmental processes[1–3]. These differentiation events include that resulting in the inactivation of all but one X chromosome in somatic cells of mammals[4]. Riggs[3] proposed that DNA methylation was responsible for initiation and maintenance of mammalian X inactivation, invoking the presence of sequence methylases with preference for half-methylated sites. Methylation has been implicated in X-chromosome inactivation on the basis of indirect evidence: the ubiquity of 5-methylcytosine, the existence of sequence-specific methylases and tissue-specific differences in methylation of differentiated genes[5,6]. There is some evidence that a gene on the inactive X remains incapable of expression even when protein superstructures are removed[7], implying that the DNA of the inactive X has undergone a permanent modification. The tissue-specific association of undermethylation with gene activity[8–17] and abundant methylation in the early embryo[15] has led to speculation that the inactive X chromosome might be highly methylated[14,15]. Recent studies of interspecies cell hybrids have shown that 5-azacytidine (5-azaC) can induce local derepression of the inactive X chromosome, presumably because the cytidine analogue has blocked methylation at relevant sites on the inactive X[18].

We have identified two cloned DNA fragments unique to the X chromosome[19] that provide a more direct means of looking for methylation differences between inactive and active X chromosomes. Using these probes, we have compared DNA methylation in placentas and skin fibroblasts from males and females. Furthermore, we have carried out direct experiments testing the ability of 5-azaC to induce reactivation of the silent X in normal human cells having enzyme markers that distinguish active from inactive X. Our results show no significant sex differences in methylation of X sequences. Moreover, studies of clonal populations of normal human cells demonstrate that the pattern of DNA methylation is not faithfully transmitted.

X-chromosome DNA methylation studies

X-chromosome-specific DNA probes provide a direct means of testing the hypothesis that the inactive X chromosome is highly methylated. The restriction enzymes *Hpa*II and *Msp*I recognize the sequence CCGG but *Hpa*II cannot cut if the internal C is methylated[20]. If DNA methylation of active and inactive X chromosomes differs significantly, the restriction fragments generated by digestion with *Hpa*II and hybridization with a labelled X-specific probe should differ between DNA of male cells with a single active X and that of female cells that have an inactive X as well.

The plasmids 0307 and 0604 contain sequences specific to the human X chromosome[19]. By means of mouse–human hybrids, the insert segments in the 0307 and 0604 plasmids have been mapped to the region on the long arm between Xq13 and Xq25. Mapping was carried out using a series of hybrids derived from mouse cells (Sv-tfm or A9) and human cells with balanced X/autosome translocation that have been used to map other X-linked genes[21,22]. The 0307 plasmid contains DNA that is transcribed as it hybridizes to total RNA extracted from normal human fibroblasts and this hybridization is RNase sensitive (Fig. 1). The 3.4-kilobase (kb) insert is a single copy sequence based on (1) analysis of reassociating kinetics using human genomic DNA[19], (2) intensity of hybridization to genomic DNA in Southern blots, relative to that obtained with a γ-globin probe[19] and (3) identification of a *Pst*I polymorphism within the sequence that behaves as expected for a single copy sequence. (Southern blot analysis of human lymphocyte DNA digested with *Pst*I and probed with 0307 usually results in bands at 7.4 and 1.0 kb. In one male with a *Pst*I restriction site polymorphism, the 7.4-kb band has been replaced by a 4.2-kb band. If the 0307 sequence were present more than once on the X, one would expect a new band in addition to the original ones.)

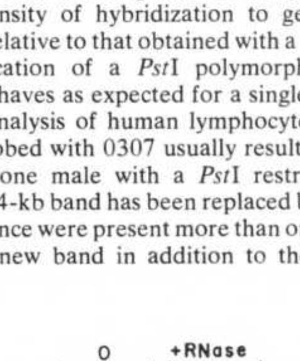

Fig. 1 Hybridization of 0307 DNA to cultured human fibroblast RNA. Total RNA, purified using hot phenol–SDS[30], was aliquoted precisely into two tubes. Pancreatic RNase A (Sigma: 5×crystallized, boiled 10 min) was added to one tube ($100\ \mu g\ ml^{-1}$) and incubated (37 °C, 2 h); the second tube was untreated. The RNA in serial dilutions was dotted onto nitrocellulose filters[16] and the filter was hybridized to 0307 labelled with ^{32}P by nick translation[19]. The final wash was at 60 °C, 0.1 SET and exposed to Kodak XAR5 X-ray film (−70 °C, 6 days). Hybridization did not occur in the absence of RNA. Parallel filters hybridized with γ-globin cDNA probe showed hybridization only to the 20-μg dots and no RNase sensitivity.

0028-0836/82/080667—05$01.00

Because the X-chromosome DNA sequence in the plasmid 0307 contains no *Hpa*II site, 0307 is a probe for methylation of *Hpa*II sites in neighbouring DNA. The 7.5-kb insert in plasmid 0604 includes a single *Hpa*II site.

Methylation patterns in male and female placentas and uncloned fibroblast cultures

Figure 2 shows the results of *Hpa*II and *Msp*I analysis of placentas (chorionic villi) and uncloned fibroblasts using probe 0307. The probe hybridizes to a single band (4.6 kb) in each of the DNA samples digested with *Msp*I (Fig. 2, lanes 1–6) so that the distance between *Hpa*II sites which span the 0307 sequence is the same in all cells. In *Hpa*II digests of male and female specimens (Fig. 2, lanes 7–12) the 0307 probe hybridizes to multiple fragments, ≥4.6 kb. Hybridization to fragments larger than 4.6 kb indicates that the internal C in the *Hpa*II recognition sequence is methylated in site(s) flanking the 0307 sequence.

The multiple bands observed in *Hpa*II digests probed with 0307 are unlikely to be the result of partial digestion. Samples were digested with excess enzyme for up to 20 h (see figure legends for details). Moreover, the number and relative intensity of bands, although variable in DNA from different individuals, are highly reproducible in repeat assays of DNA from the same individual. Furthermore, a recombinant λ phage with a 15-kb human DNA insert that includes the 0307 sequence has the *Hpa*II sites necessary to produce the multiple bands we observe. (We have identified and purified a recombinant phage containing the 0307 sequence from a *Hae*III-*Alu*I human genomic DNA library[24]. Southern blots of the recombinant phage DNA, partially digested with *Msp*I and probed with 0307, show the same 4.6–13-kb bands seen in blots of genomic DNA digested with *Hpa*II.)

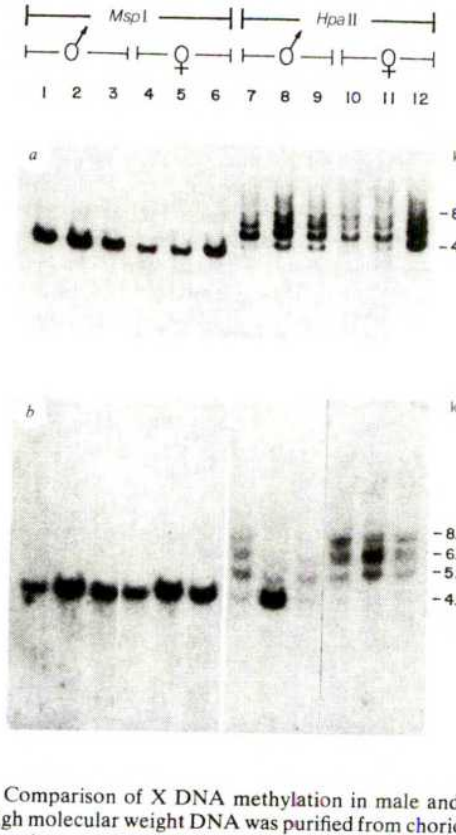

Fig. 2 Comparison of X DNA methylation in male and female cells. High molecular weight DNA was purified from chorionic villi of human placentas (*a*) and cultured human diploid fibroblasts (*b*). Southern blots[31] of enzyme-digested DNA, fractionated on 0.8% agarose gels, were hybridized with the X-specific DNA probe 0307. Digestions were carried out for 16 h with 24 U *Msp*I or *Hpa*II per μg of DNA in conditions recommended by the manufacturer. Filters washed at 65 °C in 0.1 SET were exposed to X-ray film (−70 °C, 5 days).

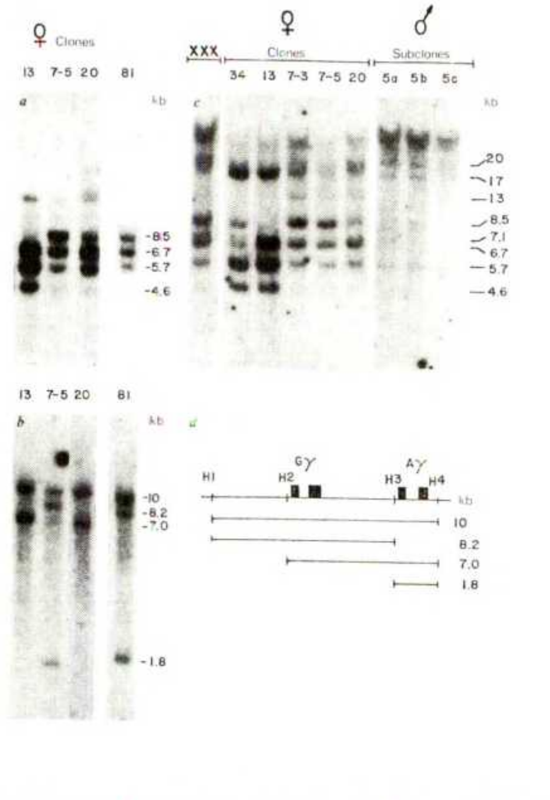

Fig. 3 DNA methylation in cloned human fibroblasts. *a*, DNA of fibroblast clones independently isolated from a culture of 46XX female cells (see text) was digested with *Hpa*II (20 U per μg DNA, 16 h). The filter was hybridized with ^{32}P-labelled 0307, washed at 55 °C in 0.1 SET and exposed to X-ray film (−70 °C, 5 days). *b*, Hybridized probe was removed from the filter used in *a* by washing (70 °C, 70% formamide, 0.1 SET). The filter was hybridized with ^{32}P-labelled γ-globin cDNA insert of plasmid JW151[33]. After a final wash (65 °C, 0.1 SET), the filter was exposed to X-ray film (−70 °C, 12 days). *c*, DNA from clones of female fibroblasts and subclones of male origin (son of the source of female clones) was digested with *Hpa*II (10 U per μg DNA for 16 h when a further 3 U enzyme per μg DNA was added and the incubation continued for 4 h). Electrophoresis was longer than in Figs 1 or 2*a* and DNA was transferred for 48 h to enhance the resolution and transfer of high molecular weight fragments. The filter was hybridized with the 0307 X DNA probe, washed (55 °C, 0.1 SET) and exposed to X-ray film (−70 °C, 5 days). Lane 1, DNA from 47XXX fibroblasts; lanes 2–4, 6, DNA from clones of the same female as in *a*; lane 5, DNA from the same clone as in lane 4, purified after five further population doublings; lanes 7–9, independent subclones derived from a single clone of male fibroblasts. *d*, *Hpa*II restriction site map of human γ-globin loci[11].

Because the 0307 sequence is single copy, yet hybridizes to multiple restriction fragments in *Hpa*II digests, the region around the 0307 sequence must be methylated differently from cell to cell. Similar studies with the second X-specific cloned DNA (0604) as probe indicate that the methylation of the single internal *Hpa*II site is also variable in both male and female fibroblasts (data not shown). The complexity of the banding pattern is not obviously related to the number of X chromosomes in the cell, as some cultures from females have as many bands as those found in trisomic cells with three X chromosomes (including two inactive ones) (Fig. 3*a*, lane 1).

Therefore, DNA methylation in the regions probed by both X-specific sequences is characterized by variability and we observe no consistent sex differences in placentas or fibroblasts.

DNA methylation in clonal populations of fibroblasts

The multiple bands we observed in chorionic villi and uncloned fibroblast cultures might be attributed to a mixed population of cells, each with a fixed but different methylation pattern. To test this hypothesis, we examined methylation in clonal populations derived from dermal fibroblasts of a female heterozygous for the X-linked marker glucose 6-phosphate dehydrogenase (G6PD) A. Clones were obtained by plating 10 cells per 60-mm dish and clonal cultures established by picking well isolated colonies, using cloning cylinders[25] to ensure that all cells in each clonal culture were progeny of a single cell. Furthermore, purity could be monitored on the basis that each clone, although of heterozygous genotype, expressed only a single G6PD isozyme, the one coded by the active X chromosome[4]. DNA was also purified from clonal populations of fibroblasts from a male, as well as derivative subclones to ensure that each colony was of homogeneous composition. The Southern blots of DNA from these clonal cultures generated by *Hpa*II digestion and hybridization with the 0307 probe show multiple bands (Fig. 3*a*, *c*) similar to those observed in uncloned cultures.

Hybridization to more than one restriction fragment in DNA from clonal populations of male cells or more than two in DNA from clones of female cells indicates that during the 20 generations required for these clonal populations to proliferate, the methylation of *Hpa*II sites in the DNA adjacent to the 0307 sequence was not fixed. Methylation in the vicinity of the γ-globin loci in the same clones is also heterogeneous, as at least two patterns were observed when the same filters were hybridized with a γ-globin cDNA probe (Fig. 3*b*).

Although the methylation of *Hpa*II sites in X DNA differs among progeny of single cells, the relative intensities of the various *Hpa*II bands generated indicate that the changes are not random. No clone produced all possible bands (compare uncloned fibroblasts in Fig. 3*c*, lane 1, with others). Moreover, the banding pattern (relative intensity and size of restriction fragments) for each clone is characteristic of that clone and is relatively stable. For example, the pattern of multiple bands produced by clone 7 remained the same after six further cell doublings (Fig. 3*c*, lanes 4, 5).

Methylation of human X chromosomes in male subclones

The difference in the banding patterns between various clones of female fibroblasts more probably reflects the unique origin of each clone. We know that clones 13 and 20 originated from different skin fibroblasts of this female because each expresses a different G6PD allele, and the other clones, as they were derived from a heterogeneous uncloned culture, may also have a unique origin.

On the other hand, subclones obtained from the homogeneous cloned population in the male are all progeny of the same cell. Therefore, our observation that three of these subclones have restriction fragments of identical size and relative intensity (Fig. 3*c*, lanes 7–9) indicates that the pattern as a whole is conserved over at least 20 population doublings. It seems that methylation of individual *Hpa*II sites is not stably inherited, but the probability that a site will be methylated is heritable.

Methylation of human X chromosomes in mouse–human hybrid cells

Although the methylation at *Hpa*II sites around the 0307 sequence is not fixed in cultured human diploid fibroblasts, methylation at these sites is more stable when the human X chromosome is present in a mouse–human hybrid cell. Figure 4 shows the Southern blot analysis of DNA from four independently derived hybrid clones (each with a different active human X) digested with *Hpa*II and probed with 0307.

The hybrid clones produced bands of the same size as those in DNA from normal human male cells, so that the sites of methylation are the same for active X DNA in either cell. However, the striking predominance of one band in each hybrid clone is evidence for greater stability of methylation of the human X in the foreign environment of the mouse–human hybrid, than in its normal habitat.

It is notable that none of the four mouse–human hybrid cells generated bands >6.7 kb. While the absence of longer bands could be mearly fortuitous, it may be that the human X chromosome in hybrid cells is in fact less methylated than in human cells.

Relationship of methylation to X-chromosome activity

One might expect that the banding pattern would be identical for clones of cells derived from the same culture, each with the same active X chromosome. However, clones 7, 13 and 34 from cultures of a heterozygous female have the same active X (maternal X), as they express the G6PD A allele, but have different banding patterns; patterns also differ for clones 81 and 20, which express the G6PD B allele (paternal X is active; Fig. 3*a*, *c*).

The presence of both active and inactive X chromosomes in these female cells may obscure specific banding patterns associated with the functional state of the chromosome. It is clear, however, that female cells do not have large *Hpa*II X DNA fragments that are not present in males. In fact, the single active X chromosome in male fibroblasts can be highly methylated in the 0307 region, as indicated by the presence of very large fragments in *Hpa*II-digested DNA from some male cells (Fig. 3*c*, lanes 7–9). However, the same sites in X chromosomes of other male cells are not methylated (Figs 2, 3*c*, lanes 7–9). The predominant band from the single active human X in various mouse–human hybrid cells can also differ in size, but tends to be of lower molecular weight, compatible with less methylation of these active X chromosomes (Fig. 4). Thus, no consistent methylation differences can be seen with respect to X-chromosome activity.

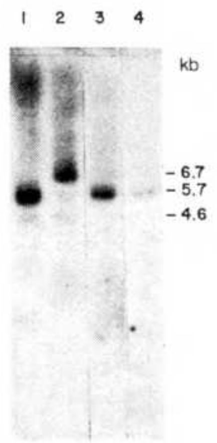

Fig. 4 Methylation in the single active human X chromosome of mouse–human hybrid cells. Purified DNA was digested with *Hpa*II (20 U per μg, 16 h). Hybridization was with labelled 0307 X DNA probe. Final wash: 55 °C, 0.1 SET; exposure: −70 °C, 5 days. Lanes 1, Sv-tfm × Kop (clone 4a)[22]; 2, Sv-tfm × 297 (clone 1)[22]; 3, A9 × Gm 1322 (clone 9-1b)[19]; 4, A9 × clone 81 (clone 6a).

Table 1 Effect of 5-azacytidine on X chromosomal phenotype

Expt	Cells per dish ($\times 10^4$)	5-azaC (μM)	Exposure (h)	Recovery (days)	Cells analysed ($\times 10^5$)	HPRT phenotype HAT^r colonies	HPRT phenotype Labelled cells	G6PD phenotype

Effect of 5-azacytidine on X-chromosome activity and methylation

Studies were carried out to determine if 5-azaC could derepress the inactive X chromosome in normal human skin fibroblasts. The two X chromosomes in female cells used for this study differ with respect to alleles at two loci, being heterozygous for G6PD A as well as for hypoxanthine phosphoribosyl transferase (HPRT) deficiency (G6PD A/B; HPRT −/+). For these experiments we treated clonal populations of cells that expressed G6PD A and HPRT deficiency (the alleles coupled on the active X). The phenotypic changes expected if 5-azaC were effective in derepressing the X were the re-expression of G6PD B and the wild-type HPRT alleles on the inactive X chromosome.

Four experiments were carried out, essentially similar but differing in the conditions of exposure to 5-azaC (see Table 1). Cells were plated at densities of 2×10^3–2×10^5 cells per dish in normal growth medium (minimal essential medium + 15% fetal calf serum, Gibco), and treated 24 h later with a fresh solution of 1–10 μM 5-azaC for 24–72 h. Cells were analysed for evidence of reactivation of the inactive X by: (1) hypoxanthine/aminopterin/thymidine (HAT) selection for cells that had acquired HPRT activity, (2) autoradiography of cells exposed to ^{3}H-hypoxanthine, or (3) G6PD electrophoresis to detect cells expressing the G6PD B allele on the inactive X.

More than 1.7×10^7 cells were treated with 5-azaC; of the 6.4×10^6 cells selected in HAT medium, we observed only one subclone that had undergone a phenotypic change. That colony (HAT^r-5-azaC-1) was able to proliferate in HAT medium, having acquired HPRT activity, but it expressed only G6PD A. Studies of mouse–human hybrids derived from this clone suggest that the change is at the HPRT locus on the active X chromosome (Fig. 5).

Although the lack of HAT^r subclones might be related to poor proliferation of cells in which derepression had occurred at the HPRT locus, the cloning efficiency for treated cells (Table 2) was sufficient to reveal reactivants if they occurred with 10^{-3} frequencies reported for mouse cells[18].

To circumvent the problem of cell proliferation, a further 6×10^6 cells were examined by autoradiography. Cells in nonselective medium were exposed to ^{3}H-hypoxanthine (NEN, 3.6-10C/M, 10 μCi ml^{-1} for 18 h); the dishes were then washed, fixed and treated with 5% trichloroacetic acid. In some cases, the cells were replated following recovery so that cell density in autoradiographs did not exceed 10^6 cells per dish. The dishes were emulsed in Kodak NTB-2, developed 1 week later, and screened microscopically for the presence of labelled cells. The assay is sensitive enough to detect individual cells that have acquired HPRT activity and only 10% normal activity is necessary for a cell to be labelled in the conditions used; however, no labelled cells were observed.

Finally, more than 20 cultures of cells totalling 3.6×10^7 cells were examined for G6PD phenotype on cellulose acetate[25] in conditions sensitive enough to detect an admixture of enzyme where the minor component is as little as 5%. However, the G6PD B allele on the inactive X was never observed.

The experimental conditions that were used induced a decrease in cloning efficiency (Table 2) similar to that reported for phenotypically altered mouse cells[26,27]. Furthermore, we observed changes in methylation at CCGG sites with both X DNA and γ-globin probes (Fig. 6); namely, a relatively greater intensity of small *Hpa*II bands with 0307 probe and the appearance of a 5.2-kb band with γ-globin probe (see Fig. 3*d*). This hypomethylation, although more subtle than that reported from more indirect observations in mouse cells[27], is compatible with changes seen in retroviral sequences from transformed chicken cells[16]. We observed an effect of treatment only in DNA from cells treated with 2 μM 5-azaC 7 days previously; none was apparent directly after treatment (Fig. 6) or with 5–10 μM 5-azaC at any time (data not shown).

Therefore, despite the use of conditions able to induce methylation changes and toxicity, we have obtained no compelling evidence that 5-azaC can derepress HPRT or G6PD loci on the inactive X chromosome in normal human cells carrying suitable markers.

Implications

The rationale for implicating DNA methylation as a mechanism for regulating gene activity is based on the presumption that, as in bacterial systems, the methylation pattern of specific DNA sequences is stably transmitted from progenitor to progeny. Our studies of clonal populations of normal diploid fibroblasts demonstrate that, in fact, methylation of the *Hpa*II sites we examined is not stably transmitted in newly replicated X DNA. There is other evidence that methylation may not be stably inherited. Methylation of the chicken thymidine kinase gene changes during propagation of the recipient mouse cells[14]. In addition, 5-azaC-induced expression of the metallothionein I gene in mouse thymoma cells, attributed to undermethylation, is unstable within five cell generations[17]. In these cases, the instability might be attributed to the foreign environment, experimental manipulation or heteroploidy. However, our results indicate that methylation is unstable in entirely normal euploid cells.

Our observations are limited to an examination of *Hpa*II sites around the two X-chromosome DNA probes that have not been characterized with regard to translation. However, we have

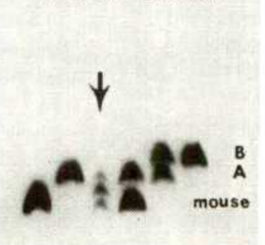

Fig. 5 G6PD electrophoresis of mouse–human hybrid showing G6PD A and heterodimer (arrow). The 5-azaC-induced HAT^r clone was hybridized to A9 mouse cell and hybrids selected in HAT[25]. Because the HPRT activity in clone HAT^r 5-azaC-1 was significantly less than that of a wild-type allele (10–20% of control), hybrids proliferated poorly and only one was able to produce sufficient cells for analysis. This hybrid clone expressed human G6PD A, mouse G6PD and the heterodimer, so that the chromosome contributing HPRT activity was that with the G6PD A allele and therefore the active X. Lanes: 1, A9; 2, HAT^r 5-azaC-1; 3, hybrid; 4, mixture of parental cells; 5, mixture of G6PD B and G6PD A fibroblasts; 6, G6PD B control.

explored a significant portion of the human X chromosome. Based on the total number of *Hpa*II fragments and the size of the largest band (see Fig. 3*c*), we estimate that with probe 0307 we have examined the methylation of at least eight *Hpa*II sites in a segment of ~20 kb in the middle of the long arm of the X. With probe 0604, we have examined another site within a 7.5-kb sequence at Xq13–25. Evidence from DNA transfer experiments and observations of local derepression at X loci suggest that modifications of DNA associated with inactivity are likely to be numerous and occur over relatively small regions of the chromosome[7,28].

Because there are no large 0307-specific *Hpa*II fragments unique to female cells, we can exclude the possibility that ubiquitous methylation accounts for inactivity of the silent X. The failure of hypomethylation, induced by 5-azaC, to reactivate alleles on the inactive X chromosome provides further evidence that X-chromosome inactivity in normal human cells is not influenced by the state of methylation at all sites along the chromosome. It is conceivable that phenotypic changes observed in transformed mouse and chick cells treated with 5-azaC[16–18,26,27,29] are not attributable to direct effects on DNA methylation. The HAT^r clone we obtained probably reflects reversion at the HPRT locus on the active X and other evidence that 5-azaC can induce mutation has been reported[29].

On the other hand, our observations do not preclude a relationship between X-chromosome methylation and transcriptional activity. The instability of methylation at individual *Hpa*II sites and the different methylation patterns observed for the active X chromosome in male cells indicate that many arrays of methylation along the X chromosome are compatible with X-chromosome activity (some highly methylated). Similarly, many methylation patterns may be compatible with X-chromosome inactivity. It is clear that several patterns of methylation at *Hpa*II sites surrounding γ-globin sequences are associated with inactivity at these loci in clonal populations of fibroblasts (Fig. 3*b*, *d*).

Table 2 Effect of 5-azaC on proliferation of fibroblast clones (expt 4, Table 1)

5-azaC (μM)	Length of exposure (h)	Clones per cells plated	Cloning efficiency	Relative cloning efficiency (%)
0		60/150	0.40	100
2	24	34/150	0.23	57.5
	48	41/150	0.27	67.6
5	24	14/150	0.09	22.5

The variety and instability of X DNA methylation patterns observed in normal human cells may explain our inability to reactivate loci on the inactive X chromosome with 5-azaC. Because 5-azaC did not induce extensive demethylation and because methylation of *Hpa*II sites seems to occur spontaneously in these cells, we may not have achieved sufficient demethylation at critical sites for X-chromosome reactivation. It is significant that the human X chromosome in the foreign environment of the mouse–human hybrid cell is probably less methylated than in normal human cells, and that the pattern is more stably transmitted. Therefore, it is not surprising that all 5-azaC-induced reactivation events have occurred in transformed mouse and chick cells[16–18,26,27], where the demethylation would be more extensive and more stable.

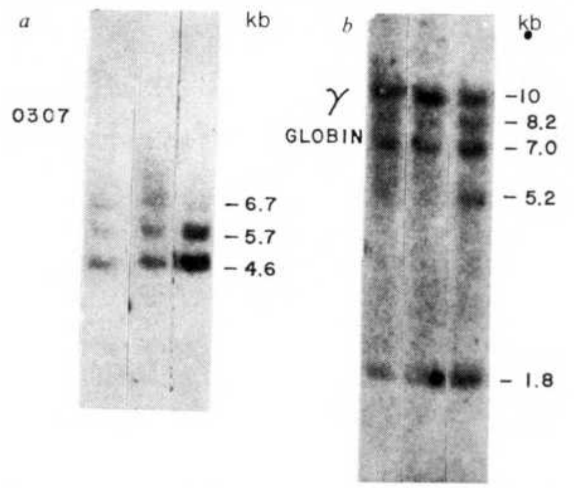

Fig. 6 Methylation of *Hpa*II restriction sites in human diploid fibroblasts treated with 5-azaC. Lanes: 1, untreated; 2, 2 μM, 48 h; 3, 2 μM, 48 h, recovery 7 days. *a*, DNA was digested with *Hpa*II (20 U per μg DNA, 16 h) and Southern blots were hybridized to the labelled 0307 probe. Final wash: 55 °C, 0.1 SET; exposure: −70 °C, 4 days. *b*, after autoradiography, the X probe was removed and the filters rehybridized with a γ-globin cDNA probe as described in Fig. 3*b* legend. Exposure: −70 °C, 7 days.

Even if methylation is involved in maintaining X-chromosome inactivity, it may be only one of several components influencing transcriptional activity. For example, the accessibility of DNA to methylases and the subsequent methylation at particular sites may depend on chromatin structure. The identical *Hpa*II-generated banding pattern seen in male subclones suggests a stable higher order determinant of DNA methylation. Similarly, the more stable methylation pattern for the human X in interspecies hybrid cells may reflect changes in the chromatin structure attributable to a foreign environment or associated with transformation (for example, acquisition of immortality, heteroploidy). Chromatin differences of this kind might explain the extensive variability in amount and distribution of 5-methylcytosine between species[5]. Further evidence for more than one level of regulation underlying X-chromosome activity are recent observations that alleles on the inactive X in normal human cells, when derepressed, produce less enzyme than those on the active X[32]. The precise relationship between X inactivation and DNA methylation remains unknown.

We thank Joyce Axelman for assistance with the azacytidine studies and Joseph B. Wiley for assistance with purification and identification of recombinant phage. This work was supported by NIH grant HD 05465.

Vitamin A and pattern formation in the regenerating limb

M. Maden

Division of Developmental Biology, National Institute for Medical Research, Mill Hill, London NW7 1AA, UK

Vitamin A and its derivatives, the retinoids, cause specific alterations in the proximo-distal pattern of regenerating axolotl limbs. In some cases complete limbs grow from carpal level amputations. If retinoids are responsible for changing the positional information of limb cells, these compounds may represent valuable probes for investigating the molecular basis of pattern formation.

VARIOUS experimental approaches have been used to study pattern formation. The original approach, begun in the last century, is to alter the spatial relationships of the system under study by transplanting tissue to different sites and observing the resultant disruption of the pattern. In the limb, the system studied here, this approach has revealed organizing regions such as the zone of polarizing activity[1,2], the polarizing zone[3] and the apical ectodermal ridge[1,4], and the beginnings of a theoretical framework into which the phenomena can be fitted[5]. An alternative approach is to search for substances which alter pattern formation in specific ways, for example, the effect of lithium on early development[6]. Unfortunately, in this case subsequent investigations did not prove particularly valuable in advancing our understanding of the molecular basis of pattern formation. Here I report that vitamin A and its derivatives, the retinoids, alter pattern formation specifically in the proximo-distal axis of regenerating axolotl limbs. If these effects are due to changes in the positional information of limb cells caused by retinoids, these compounds may be used in future research to elucidate the molecular nature of positional information.

Niazi and Saxena[7] studied the effects of retinol palmitate on hindlimb bud regeneration of *Bufo* tadpoles. In addition to its inhibitory properties, they found several cases of duplicated or triplicated regenerates, some of which consisted of more than those distal parts of the limb removed by amputation. These results seemed not only to contradict the rule of distal transformation[8], but also were unique in increasing the potency of blastemal cells as all other substances which have been administered to regenerating limbs have caused deficiencies[9,10]. Thus I decided to investigate further this phenomenon in the regenerating limbs of larval axolotls, *Ambystoma mexicanum*, an animal commonly used for regeneration studies.

Effect of vitamin A

To confirm the existence of the effect described by Niazi and Saxena, I amputated the forelimbs of 14 animals through the mid-radius and ulna. The animals were immediately placed in a solution of retinol palmitate (15 IU ml^{-1}, made up in tap water) for 12 days and then transferred to normal water. An equal number of control animals were allowed to regenerate in pure tap water. After 1 month the limbs were fixed and stained. In contrast to the high mortality caused by hypervitaminosis A in *Bufo* tadpoles[7] (and confirmed by my own results on *Rana* tadpoles), axolotls seemed immune. All experimental animals survived and seemed even healthier than normal.

In control limbs, all the elements removed by amputation were regenerated (Fig. 1*a*), whereas after retinol palmitate treatment, every limb (28 in all) was abnormal in the proximo-distal sequence of regenerated elements. The severity of the effect varied and could be separated into four classes (Table 1). The least severely affected were those limbs in which there was an extra row of carpals (Fig. 1*b*). In the next group an additional length of radius and ulna had been intercalated, which fused with the stump radius and ulna resulting in an abnormally long segment (Fig. 1*c*). The third class comprised limbs in which a complete additional radius and ulna had been intercalated, resulting in a tandem repeat of that segment (Fig. 1*d*). The most severe effect was the additional presence of the distal part of the humerus (Fig. 1*e*). Most of the abnormalities observed (46%; Table 1, top row) consisted of extra carpals, the least severe effect.

In all other aspects, however, these experimental regenerates were normal: the digits were in the normal sequence with the

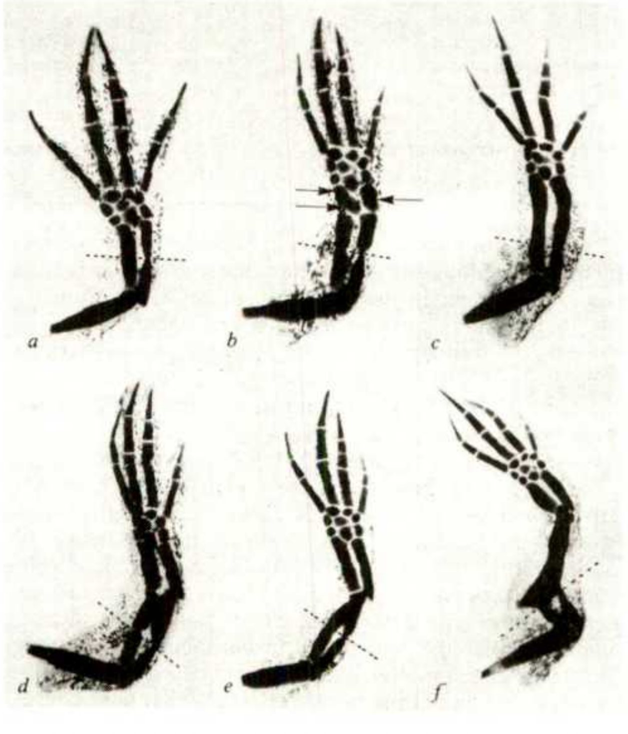

Fig. 1 Cleared whole mounts of regenerated limbs stained with Victoria blue. All limbs were amputated through the mid-radius and ulna, the broken line marking the amputation plane. *a*, Control. The elements removed by amputation (distal radius and ulna, 8 carpals and 4 digits) have been replaced. *b–e*, Limbs treated with 15 IU ml^{-1} retinol palmitate for 12 days. *b*, Three extra cartilages (arrows) have been produced which resemble carpals. *c*, An abnormal length of radius and ulna has been regenerated making this segment grossly out of proportion. *d*, A complete extra radius and ulna has been produced in tandem. *e*, The radius and ulna have fused into the distal end of the humerus with a perfect elbow joint followed by a complete radius and ulna and hand. *f*, A limb regenerated after 15 days in 75 IU ml^{-1} retinol palmitate; here a complete limb has been produced distal to the amputation plane. Magnifications: *a*, ×9; *b*, ×8; *c*, ×7.6; *d*, ×7.6; *e*, ×7; *f*, ×6.

Table 1 Effects of varying concentrations and lengths of exposure to vitamin A (retinol palmitate) after forelimb amputation through the mid-radius and ulna

Length of exposure (days)	Concentration of vitamin A (IU ml^{-1})	No. of cases	Type of regenerate: Normal (Fig. 1*a*)	Extra carpals (Fig. 1*b*)	Extra part radius and ulna (Fig. 1*c*)	Extra full radius and ulna (Fig. 1*d*)	Extra part humerus (Fig. 1*e*)	Extra full humerus (Fig. 1*f*)
12	15	28	0	13(46%)	7(25%)	5(18%)	3(11%)	0
10	30	10	0	0	7(70%)	3(30%)	0	0
15	30	8	0	0	1(13%)	2(25%)	6(62%)	0
10	75	10	0	0	0	5(50%)	5(50%)	0
15	75	8	0	0	0	0	1(13%)	7(87%)

Length of exposure is from the day of amputation. The types of regenerate are exemplified in Figs 1, 2 and described in more detail in the text.

correct phalangeal number, there were no alterations in the anteroposterior axis (compare Fig. 1*a* and *b–e*) nor any duplications or triplications as found in *Bufo* tadpoles[7], and serial sections of four limbs revealed normal muscle patterns in the extra segments. Thus only the proximo-distal sequence of elements seemed to be affected in that varying lengths of extra pattern were intercalated between the amputation plane and the appropriate distal level.

Effect of increasing concentration and length of exposure

Four groups of five animals each had their forelimbs amputated as before, and were placed in 2× concentration (30 IU ml^{-1}) or 5× concentration (75 IU ml^{-1}) of retinol palmitate for 10 or 15 days. Neither concentration caused increased mortality and the effects of these treatments on pattern formation are shown in Table 1. Increasing the concentration caused a greater amount of pattern to be intercalated between the amputation plane and the appropriate distal level (compare rows 1, 2 and 4) such that after 10 days in 75 IU ml^{-1}, half the limbs had tandem repeats of the radius and ulna as well as the distal humerus. Similarly, increasing the time of exposure caused more pattern to be intercalated so that after 15 days in 75 IU ml^{-1}, a new class of abnormality appeared (Table 1, bottom row)—a complete limb regrew from the amputation plane, resulting in a proximo-distal sequence of elements of humerus, proximal radius and ulna (stump), full humerus, radius and ulna, carpals and digits (Fig. 1*f*).

Thus by increasing the concentration of retinol palmitate and the length of exposure, the level at which the limb was repeated became more and more proximal, finally resulting in a complete limb being regenerated from the distal amputation plane.

Morphological observations

While observing the animals during these experiments it became apparent that retinol palmitate was inhibiting the rate of regeneration. Normal regeneration in control animals progressed rapidly—cone stage on day 10, notch stage by day 12 and by day 18 four digits were present in outline. In the presence of retinol palmitate a progressive retardation of regeneration with increasing concentration was revealed and in 75 IU ml^{-1}, there were no external signs of regeneration. Immediately after removal to pure water, blastema formation commenced, consistent with the known inhibitory effects of retinoids on cell division. However, during the period in which there was no blastema development, preparations for the dramatic changes in pattern formation must, nevertheless, have been occurring.

Other amputation levels

The above experiments were repeated in animals whose forelimbs had been amputated either through the mid-humerus or through the carpals.

Amputation through the humerus (56 cases in all) gave the same results as those described above, that is, increasing the concentration of and length of exposure to retinol palmitate caused the level at which the limb was repeated to become more proximal. For example, after 12 days at the lowest concentration (15 IU ml^{-1}) the regenerates had abnormally long humeri, whereas after 15 days in 30 or 75 IU ml^{-1}, 67% and 87% respectively of the cases regenerated a complete new limb from the amputation plane (Fig. 2*a*).

After amputation through the carpals (46 cases in all), many regenerates had digital deficiencies such as missing or fused digits at the lower concentrations. This was the only series of experiments in which these abnormalities occurred consistently. At 15 and 30 IU ml^{-1} the only other effect on regeneration was the production of an extra row of carpals (for example, see Fig. 1*b*). However, at 75 IU ml^{-1}, six out of eight limbs regenerated complete limbs from the carpals (Fig. 2*b*). Furthermore, in two of these cases the most proximal element regenerated was not just the proximal epiphysis of the humerus, but also the glenoid cavity and part of the scapula (Fig. 2*c*).

By comparing the regenerates obtained from these three amputation levels of the forelimb, one further conclusion was drawn. The concentration of retinol palmitate needed to induce the regeneration of a complete limb decreased as the amputation plane became more proximal, that is, only the longest time at the highest concentration (75 IU ml^{-1}) led to regeneration of complete limbs from the carpal level, whereas 30 IU ml^{-1} produced the same result from amputations at the humerus level.

Effect on hindlimbs

The whole range of experiments was repeated on a total of 133 hindlimbs. At high concentrations of retinol palmitate, complete limbs were regenerated from amputations through the mid-femur or mid-tibia and fibula (Fig. 3*a*) and with lower concentrations and shorter exposure times the extent of serial repetition decreased. In the cases where whole limbs regenerated, not only was there a complete femur, but also a

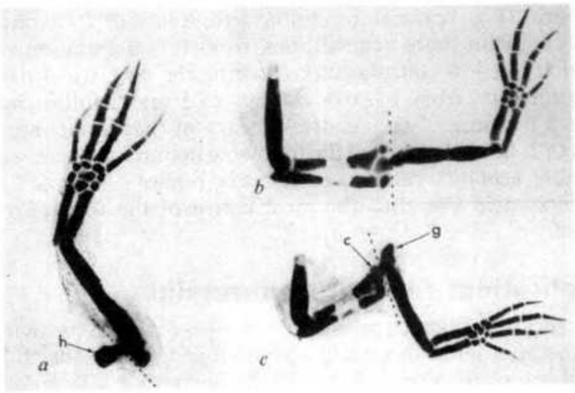

Fig. 2 Forelimbs placed in retinol palmitate (75 IU ml^{-1}) for 15 days. Broken lines mark the amputation planes. *a*, Proximal to the amputation plane is the remaining small part of the original humerus (h). Distally a complete limb has regenerated. *b*, Amputation through the carpals. Three carpals remain in the stump (radiale, intermedium and ulnare) and distally a complete limb has regenerated. *c*, Same as *b* but in this case part of the pectoral girdle (g) including the glenoid cavity has also been produced. Magnifications: *a*, ×6; *b*, ×5; *c*, ×5.

Table 2 Effects of 15-day exposure to various retinoids after amputation through the mid-radius and ulna or tibia and fibula

			Type of regenerate						
Compound		No. of cases	Normal	Extra carpals	Extra part radius and ulna	Extra full radius and ulna	Extra part humerus	Extra full humerus	Relative effectiveness
Retinol palmitate	(0.6 mM)	20	3(15%)	0	3(15%)	8(40%)	6(30%)	0	54
Retinol acetate	(0.6 mM)	13	0	0	12(92%)	0	1(8%)	0	43
Retinol palmitate	(0.12 mM)	20	15(75%)	0	5(25%)	0	0	0	10
Retinol acetate	(0.12 mM)	20	18(90%)	0	2(10%)	0	0	0	4
Retinol	(0.12 mM)	16	0	0	4(25%)	3(19%)	8(50%)	1(6%)	68
Retinoic acid	(0.12 mM)	15	0	0	0	3(20%)	9(60%)	3(20%)	80

Same classes of abnormalities as in Table 1. All compounds were obtained from Sigma. Retinol palmitate, retinol acetate and retinoic acid were dissolved in water, retinol in dimethyl sulphoxide.

socket, acetabulum and what appeared to be a small part of the pelvic girdle (Fig. 3*a*, *b*). Complete limbs were not regenerated from tarsal level amputations even at 75 IU ml^{-1} as in the case of forelimbs. Subsequent experiments revealed that a concentration of 150 IU ml^{-1} was needed for this to occur (Fig. 3*b*). This confirmed a trend which was apparent from a comparison of fore- and hindlimb experiments, that any one concentration and time had a greater effect (that is, caused regeneration to commence from a more proximal level) in the forelimb than in the hindlimb.

Effectiveness of other retinoids

I tested retinol palmitate, retinol acetate, retinol and retinoic acid to determine their comparative efficacy in inducing pattern abnormalities. Two concentrations were used: 0.6 mM (equivalent to 75 IU ml^{-1} retinol palmitate) and 0.12 mM (equivalent to 15 IU ml^{-1} retinol palmitate). Five animals whose fore- and hindlimbs had been amputated through the radius and ulna or tibia and fibula were immersed in each of the test solutions for 15 days (a total of 160 limbs). At the highest concentration, all the animals kept in retinol died, as did three out of five in retinoic acid with the remaining two not regenerating. One animal in retinol acetate died. Thus only retinol palmitate and retinol acetate could be compared in this experiment (Table 2). In 0.6 mM retinol palmitate, as before there was a spread of abnormalities, with most producing an extra radius and ulna in tandem (Fig. 1*d*) or an extra humerus also (Fig. 1*e*). The effects of retinol acetate were less severe, most consisting of an abnormally long radius and ulna (Fig. 1*c*).

At the lower concentration (0.12 mM; Table 2, rows 3–6), retinol palmitate had only minor effects; most of the regenerates were normal and the remainder had an abnormally long radius and ulna. Again retinol acetate was less effective. However, in 0.12 mM retinol the majority of limbs had an extra part humerus (Fig. 1*e*), and in retinoic acid, a further 20% of cases had complete limbs regenerating from the amputation plane even at this low concentration. Scoring the severity of pattern abnormalities from 1 (extra carpals) to 5 (extra full humerus) gave a measure of the relative efficacy of these four retinoids (Table 2, last column) and the following heirarchy was revealed: retinol acetate < retinol palmitate < retinol < retinoic acid. Retinoic acid was thus the most active of the four retinoids tested.

Implications for pattern formation

The most obvious conclusion from these results is that the regenerated limbs described above all contravene the 'rule of distal transformation'[8]. It has been shown that cells from any one level can only generate more distal limb levels during intercalary regeneration[11,12] or regeneration from a reversed stump[13,14] nor can they be forced to transform proximally in normal conditions[12]. However, it is now clear that if conditions are changed by the addition of retinoids this rule no longer applies.

As the profound changes brought about by retinoids occur while blastemal development and presumably cell division is inhibited, it follows that changes in pattern do not necessarily require cell division. They can be totally independent of growth, although subsequent proliferation is needed to manifest any alterations that have occurred. Thus pattern formation and growth control may be specified by different mechanisms. I have argued elsewhere[15] that limb regeneration consists of two phases, an early morphallactic phase during which positional values are reassigned without cell division, followed by a period of growth when the remaining discrepancies are evened out. This scheme agrees in all respects with the results reported here.

One possible explanation of the results is that the time delay itself is responsible for the extra pattern generated. However, a similar retardation occurs after amputated limbs have been denervated, a procedure which removes the source of neurotrophic factor and inhibits cell division[16], but in contrast to retinoid treatment, when nerves are allowed to regrow into such limbs, only those elements that were removed by amputation are regenerated[17]. Therefore time delays *per se* do not cause changes in pattern.

Possible mode of action of retinoids

Research into the cellular effects of retinoids has mainly involved mammalian tissues and even within this constraint many contradictory results have been reported. Thus extrapolation to amphibian tissues is of limited value, but perhaps two effects are noteworthy. One is the blocking of cell communication by gap junctions[18] (although an increase in gap junction formation has also been noted[19]). Cellular communication must surely have a vital role in the normal process of

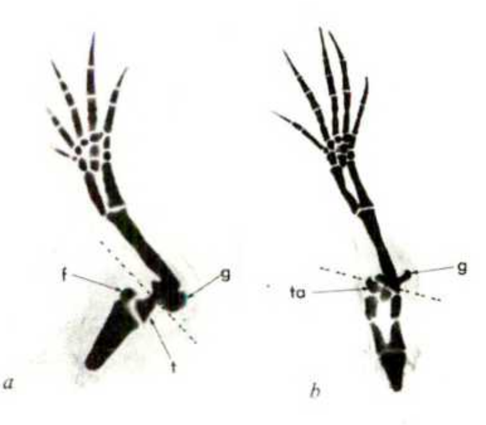

Fig. 3 Hindlimbs regenerated after vitamin A treatment. Broken lines mark the amputation planes. *a*, Retinol palmitate (75 IU ml^{-1}) for 15 days. The remaining parts of the tibia (t) and fibula (f) can be seen and not only has a whole limb been produced distally but also part of the pelvic girdle, the acetabulum (g). *b*, Amputation through the tarsals and retinol palmitate (150 IU ml^{-1}) for 15 days. The remaining tarsals (ta) can be seen and a complete new hindlimb including part of the girdle (g) has regenerated distally. Magnifications: *a*, ×6; *b*, ×6.

regeneration and any interference could cause pattern abnormalities. The other concerns speculations on the role of the cell surface in pattern formation. It has been suggested that positional information is encoded in the lengths of sugar chains on surface glycoproteins[20] and retinol does indeed act as a sugar donor in glycosyl transfer reactions[21]. In the nearest experimental system to that described here, that is, chick or mouse limb bud mesenchyme, retinoids cause specific alterations in cell-surface glycoproteins[22,23]. These speculations must await further research, but hopefully we now have a probe for investigating the molecular nature of positional information during pattern formation, at least in the limb.

I thank Katriye Mustafa for technical assistance in all aspects of this work.

Observations of intensity transitions in the X-ray emission from the black-hole candidate Cygnus X-1 (see ref. 1 and refs therein) were made by the Hakucho satellite[2] during the summer of 1980 and are reported here. In addition, we report the results of hard (20–120 keV) X-ray observations of Cyg X-1. These data were obtained during the 'high' intensity state by balloon-borne mercuric iodide detectors, and are compared with data obtained at similar energies approximately 1 month earlier (A. Sheepmaker *et al.*, in preparation) during the 'low' intensity state.

Cyg X-1 was observed to be in a 'high' state by the Uhuru satellite[3] from December 1970 (its first observation of the source) to April 1971 and again during 1975 by the Ariel V (refs 4–6), and OSO-8 instruments[7], as well as the Astronomical Netherlands Satellite[8]. Subsequent observations at many different X-ray energies have indicated that Cyg X-1 has been in an extended 'low' state since early 1976. In his review of Cyg X-1 (ref. 1), Oda has summarized the light curves and spectral information which were published up to 1977. During the transition to a 'high' state, the soft (< 10 keV) and hard (> 10 keV) X-ray intensities seem to be anticorrelated, that is, a 'high' state below 10 keV is associated with a substantial decrease in the X-ray intensity above 10 keV.

For the work reported here, soft X-ray observations (1–30 keV) were made with the scanning y-axis detectors on board the Hakucho satellite. The y-axis detector system consists of a pair of Xenon-filled proportional counters (SFX-VI and SFX-V2) with a 1.7° × 32° FWHM field of view. Each of the two counters has an effective area of 32 cm^2. Only the SFX-V1 data were used in this analysis as the SFX-V2 field of view contained Cyg X-3 during most of the observations. The satellite spins at 6 r.p.m., so that 3,000 transits of a given source are available during the five daily 10-min passes above the tracking station at Uchinora, Japan. The source transits are superposed and corrected for aspect transmission and Earth occultation. Background is also subtracted. (For further details on the Hakucho satellite see ref. 9.)

Figure 1 shows part of the X-ray light curve obtained with the Hakucho y-axis detectors during 1980. Each point represents the daily average X-ray intensity from Cyg X-1. Two 'high' states are clear: the first lasted at least 15 days, and was followed by a decrease over ~25 days to the pre-transition level; a second increase was observed ~4 months later. This transient event resulted in the highest measured intensity shown in Fig. 1 and began after JD 2444551.66 but before JD 244553.56 (binary phase 0.05 and 0.39 respectively). Thus the rise time was less than 1.9 days. This increase was quite brief, with the 'high' state persisting for only 2 days. The erratic variability seen during the 1980 observations is similar to that observed in 1975 and reported by Holt *et al.* using the Ariel V All Sky Monitor[6].

Also indicated in Fig. 1 are the dates when hard X-ray (20–200 keV) balloon observations of Cyg X-1 took place. The 'low' state observations (8 May 1980) were performed by the MIT/Leiden Balloon Group and will be reported separately (A. Scheepmaker *et al.* in preparation). The 'high' state observations (28 June 1980) constituted the first use of a mercuric iodide X-ray detector[17] in an astronomical experiment. The detector consisted of 11 HgI_2 crystals with a total effective area of 7.6 cm^2. The detector assembly (crystals and preamps) was enclosed within a cylindrical NaI scintillator well (active anticoincidence shield) which rejected charged particles and γ rays. The preflight energy resolution of the detectors ranged from 2–6 keV FWHM at 60 keV and remained stable during the 13-h flight from Palestine, Texas. The gondola containing the detector was

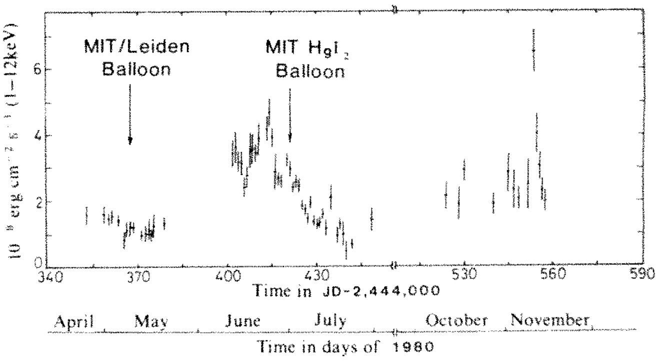

Fig. 1 Soft X-ray (1–12 keV) light curve of Cyg X-1 obtained with the Hakucho satellite. Two 'high' states are evident. The first began before 10 June 1980 and the second transient event occurred in November 1980. Also shown are the dates of simultaneous observations in hard X-rays by balloon-borne instruments.

0028–0836/82/080675—02$01.00

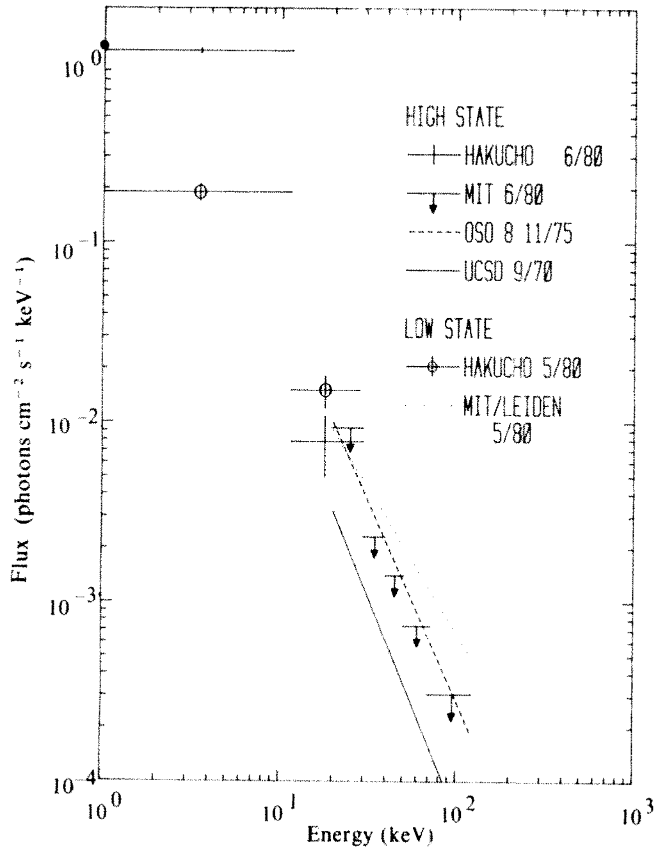

Fig. 2 X-ray spectra taken before and after the 'high' state transition of Cyg X-1 in late May/early June 1980. Data were obtained with the Hakucho satellite and with balloon-borne hard X-ray detectors. The Hakucho data points for high and low states are averages for 12–30 June 1980 and 1–19 May 1980, respectively. Also included are representative hard X-ray spectra taken during previous high states[7,11].

launched on an 11×10^6 ft^3 balloon at 00.15 UT on 28 June 1980 and floated west for 13 h at an average altitude of 40 km (~ 2.9 g cm^{-2}). Maximum exposure to Cyg X-1 occurred at 08.30 UT 28 June 1980. The detectors were calibrated using an on-board ^{241}Am source for 2 min out of every hour. The counts for each separate HgI$_2$ detector were binned in 64-s intervals in coarse energy channels, 10 keV wide. The detector counts were then summed to give the total counts per energy channel per 64 s.

Total exposure to the X-ray source was calculated as a function of time, taking into account aspect (azimuth, latitude, sidereal time, and field of view of individual HgI$_2$ detectors), atmosphere and detector window transmission, detector efficiency, and dead time. The maximum exposure to Cyg X-1 at transit was 37% over the 50–70 keV energy range. For each energy channel, an effective time on source, $t_{\text{eff}} = \sum_i t_i \varepsilon_i$, was calculated and used to convert observed counts to a photon flux at the top of the atmosphere. Here, t_i refers to an individual time bin and ε_i is the total exposure, including atmospheric and aspect corrections as discussed above. There was less than a 2σ detection in all energy bands.

Cygnus X-1 passed through the field of view in 95 min resulting in 83 min of 'on source' data (that is, 5 min were occupied by calibrations and 7 min were lost due to telemetry dropouts); 40 min before and after this period were averaged and used as background.

Figure 2 shows the 2σ upper limits derived for the hard X-ray spectrum during the 28 June 1980 Cyg X-1 'high' state observation. Also indicated are the results from the 8 May 1980 hard X-ray observations by Scheepmaker *et al.* (in preparation) which were obtained when Cyg X-1 was in the 'low' state, as well as representative hard X-ray measurements during the 1971 and 1975 'high' states. The 1–12 keV and 12–30 keV X-ray intensities from the Hakucho observations have been averaged over the high state and the low state separately. As can be seen in Fig. 2, the hard X-ray intensity is anticorrelated with the soft X-ray intensity; the pivot point occurs for an energy below 30 keV. The best fit power law for the Hakucho measurements gives a photon number spectral index of 1.5 ± 0.1 for the low state and 2.7 ± 0.2 for the high state. Using detectors on HEAO 3, Ling *et al.* (ref. 10 and personal communication) also recorded a continuous decrease in the hard X-ray intensity (48–183 keV) from 19 May 1980 until at least 2 June. The spectral anticorrelation reported here was also observed in previous low to high state transitions[7,11] and seems to be a consistent feature of the bimodal behaviour of Cyg X-1.

Previous observations have established that the spectrum varies with time during the different intensity states and is not well represented by a simple relation (for example, power law or exponential). This has led to the idea that the soft component of the spectrum may originate in the outer optically thick region of an accretion disk surrounding the central compact object, whereas the hard component arises in an optically thin, hot inner region[12]. The observed time scales for the transition to, and decay from, a 'high' state are consistent with theoretical calculations for the evolution of a standard accretion disk[13], and suggest fluctuations in the accreted stellar wind or changes in the optical depth of the gas at the outer edge of the disk (see refs 1, 14 and refs therein). Spectral anticorrelation has also been used to explain the energy dependence of the short term variability (milliseconds to seconds)[15]. A numerical model proposed by Ichimaru[16] shows that two physically distinct states can exist in the accretion disk depending on whether the radiative loss is smaller or larger than the viscous heating near the outer boundary (that is, a transition is expected to occur for $\dot{M}/T^2 \sim 5 \times 10^3$ g s^{-1} K^{-2} where $\dot{M}$ is the accretion rate and T is the gas temperature at the outer edge of the disk). Thus, the middle part of the disk may become optically thick (high state) or optically thin (low state).

We conclude that Cygnus X-1 returned to its high state in 1980 after an apparent 4.5-yr interval in the low state. Note that this time period is similar to the 4-yr interval between the first and second observed transitions[3,4]. We have established that the soft and hard X-ray intensities are anticorrelated in the transition between the two distinct states and we believe that any theoretical model of the bimodal behaviour of Cyg X-1 must account for this spectral anticorrelation.

We thank all the members of the Hakucho team for their contributions to the observations; Drs H. Inoue, K. Makishima and T. Murakami for help in the data analysis and preparation of the manuscript; Robert Kubara and the launch crew at the National Center for Atmospheric Research; and Dick Lynn, Carol Ortale, Wayne Schnepple and John Warren for assistance. A. Scheepmaker provided data from the MIT/Leiden 1980 balloon flight before publication. L.R.C. acknowledges support from Zonta International during part of this work. This research was sponsored in part by NASA under grants NAGW-14 and NSG7339.

Quantum conformal fluctuations in a singular space–time

T. Padmanabhan & J. V. Narlikar

Tata Institute of Fundamental Research, Bombay 400 005, India

The cosmological solutions of Einstein's general relativistic equations lead inevitably to space–time singularities[1]. However, general relativity is only an approximation to a fully quantized theory of gravity and we need to consider whether singularity persists in the quantum domain. Although a full quantum theory of gravity has not yet been developed, we show here that the above question can be tackled in a simplified model where only the conformal degree of freedom is quantized. Previous applications of this technique had shown that in specific cases the quantum conformal fluctuations (QCF) from the classical solutions diverge at the classical singularity, thus rendering the classical solution physically meaningless[2,3]. Recently one of us (J.V.N. ref. 4) has generalized this result to cover all dust cosmologies. Here we show that this conclusion is applicable to even more general types of cosmological singularities.

To arrive at this result we draw on the mathematical details of previous work; in particular, we make extensive use of the formalism developed in ref. 4.

Classical equations of general relativity are derived from the variation of the action S given by

$$S=\frac{1}{16\pi}\int R\sqrt{-g}\,\mathrm{d}^4x+\int \mathscr{L}_{\mathrm{m}}\sqrt{-g}\,\mathrm{d}^4x \qquad (1)$$

We have taken $c=1$ and $G=1$. As we are discussing quantum phenomena we will also take $\hbar=1$, thus making the Planck length the basic unit. $\mathscr{L}_{\mathrm{m}}$ is the lagrangian density for matter.

In the thin sandwich problem[5] of classical gravity, if data are given on initial and final hypersurfaces Σ_1 and Σ_2, $\delta S=0$ determine the geometry of the space–time sandwiched between Σ_1 and Σ_2. The initial and final data are specified by 3-geometries ${}^{(3)}\mathscr{G}_1$ and ${}^{(3)}\mathscr{G}_2$. In the quantum problem there is no unique sequence of 3-geometries leading from Σ_1 to Σ_2. Instead we have a probability amplitude $K[{}^{(3)}\mathscr{G}_2, \Sigma_2; {}^{(3)}\mathscr{G}_1, \Sigma_1]$ for the system to have the specified initial and final data. The kernel K is formally written as the Feynman functional integral

$$K[{}^{(3)}\mathscr{G}_2, \Sigma_2; {}^{(3)}\mathscr{G}_1, \Sigma_1]=\int \exp iS[\mathscr{G}]\mathscr{D}\mathscr{G} \qquad (2)$$

where $S[\mathscr{G}]$ is the action for an arbitrary geometry $\mathscr{G}$ which satisfies the given boundary conditions. If we are considering only the conformal degrees of freedom we have to take all geometries given by the metrics

$$g_{ik}=\Omega^2\bar{g}_{ik} \qquad (3)$$

where Ω is a function of space and time ($i=0,1,2,3$), while $\bar{g}_{ik}$ is the metric tensor describing the solution of the classical problem (all physical quantities pertaining to the classical solution carry an overbar).

Using a time coordinate t to label the spacelike hypersurfaces Σ_1, Σ_2 as t_1, t_2 we may rewrite equation (2) as

$$K[\Omega_2, t_2; \Omega_1, t_1]=\int \exp iS[\Omega]\mathscr{D}\Omega \qquad (4)$$

with

$$S[\Omega]=\frac{1}{16\pi}\int(\bar{R}\Omega^2-6\Omega_i\Omega^i)\sqrt{-\bar{g}}\,\mathrm{d}^4x+\int\mathscr{L}_{\mathrm{m}}\sqrt{-g}\,\mathrm{d}^4x \qquad (5)$$

The lack of a unique space–time geometry in the quantum regime may also be expressed through a wavefunction Ψ which 'propagates' with the kernel K:

$$\psi(\Omega_2, t_2)=\int K[\Omega_2, t_2; \Omega_1, t_1]\psi(\Omega_1, t_1)\mathscr{D}\Omega_1 \qquad (6)$$

A physical interpretation can be given to the above relation by choosing a Gaussian wavepacket form for $\psi(\Omega_1, t_1)$ and then studying its dispersion as the final hypersurface Σ_2 approaches the singularity. For the examples discussed in refs 2 and 3, it was shown that while the 'mean' of the wavepacket stays on the classical solution $\Omega=1$, its dispersion diverges as the classical singularity is approached.

It was shown in ref. 4 that the above results were in fact part of a general result which was valid for all singular space–times containing only dust. By a similar analysis it can be shown that whenever $S[\Omega]$ is a quadratic functional in Ω and its derivatives, the kernel can be writtten as

$$K[\Omega_2, t_2; \Omega_1, t_1]=F(t_2, t_1)\exp[i\bar{S}] \qquad (7)$$

where $F(t_2, t_1)$ depends only on t_2 and t_1, and

$$\bar{S}=\sum_{P=1}^{2}\sum_{Q=1}^{2}\frac{3}{8\pi}\iint A_{PQ}(\mathbf{x}_P, t_P; \mathbf{x}'_Q, t'_Q)\times\Omega_P(\mathbf{x}_P)\Omega_Q(\mathbf{x}'_Q)\,\mathrm{d}^3\mathbf{x}_P\,\mathrm{d}^3\mathbf{x}'_Q \qquad (8)$$

The coefficients A_{11} and A_{22} are given by certain integrals involving the retarded Green's function $G(\mathbf{x}_2, t_2; \mathbf{x}_1, t_1)$ of a scalar wave equation determined by the background classical geometry and the source. In the dust case discussed in ref. 4, the scalar wave operator is simply $\bar{\Box}+\bar{R}/6$.

The interesting part of $\bar{S}$ in equation (8) is, however, the cross term containing A_{12}, which retains the memory of the initial wavefunction at $t=t_1$. The coefficient A_{12} is given by

$$A_{21}(\mathbf{x}_2, t_2; \mathbf{x}_1, t_1)=A_{12}(\mathbf{x}, t_1; \mathbf{x}_2, t_2)=[G(\mathbf{x}_2, t_2; \mathbf{x}_1, t_1)]^{-1} \qquad (9)$$

Suppose now that G diverges as the space–time singularity is approached. We then have $A_{12}\to 0$ and a decoupling of the final wavefunction from the initial one. This is precisely the state of complete uncertainty of the final state represented in the wavepacket case by infinite dispersion.

In ref. 4 the divergence of G at the singularity was deduced from the conformal invariance of the operator $\bar{\Box}+\bar{R}/6$. However, the result also seems to be valid for other cases. For example, it was shown recently[6] that the QCF diverge for a Robertson–Walker universe containing a massless scalar field. The QCF also diverge at the singularity of the empty Kasner universe[7]. These results suggest that we should look for a proof of the divergence of G in a fairly general scenario as follows.

Belinskii *et al.*[8] argued that a general approach to the space–time singularity can be described by a succession of Kasner type solutions, in which the Universe contracts along two axes and expands along the third. (We have reversed the direction of time so that $t\leq 0$ and the final singular state is described by $t=0$.) Without going into detail we will simply accept the claim that number, 8, of arbitrary functions in the Belinskii *et al.*[8] solution makes it a general solution of Einstein's equations.

Belinskii *et al.*[8] have argued that near the space–time singularity the contributions from $\mathscr{L}_{\mathrm{m}}$ can be neglected and the wave operator for our Green's function then becomes simply $\bar{\Box}$. We therefore have to show that in the space–time of their model the Green's function of the wave equation

$$\bar{\Box}\bar{G}(\mathbf{x}_2, t_2; \mathbf{x}_1, t_1)=[-\bar{g}(\mathbf{x}_1, t_1)]^{-1/2}\delta_4(\mathbf{x}_2, t_2; \mathbf{x}_1, t_1) \qquad (10)$$

diverges as $t_2\to 0$.

The line element of the Belinskii *et al.* model is given by

$$\mathrm{d}s^2=\mathrm{d}t^2-\gamma_{\alpha\beta}\mathrm{d}x^\alpha\,\mathrm{d}x^\beta, \quad \alpha,\beta=1,2,3 \qquad (11)$$

$$\gamma_{\alpha\beta}=\sum_{\mu=1}^{3}|t|^{2p_\mu}l_{\mu\alpha}l_{\mu\beta} \qquad (12)$$

where p_μ, $l_{\mu\alpha}$ are functions of space coordinates. As in the Kasner universe, the p_μ satisfy

$$\sum_{\mu=1}^{3}p_\mu=\sum_{\mu=1}^{3}p_\mu^2=1 \qquad (13)$$

Simple algebra shows that close to the singularity the Green's function is given by

$$G(\mathbf{x}_2, t_2; \mathbf{x}_1, t_1)\cong\frac{\delta_3(\mathbf{x}_2, \mathbf{x}_1)}{f(\mathbf{x}_2)}\ln\left|\frac{t_1}{t_2}\right| \quad 0>t_2>t_1 \qquad (14)$$

0028-0836/82/080677—02$01.00

while $G = 0$ otherwise. The function f depends on the space coordinates. We are interested in the behaviour of the Green's function as $t_2 \rightarrow 0$, the singular epoch.

From equation (14) we have $G \rightarrow \infty$ logarithmically as $t_2 \rightarrow 0$, leading to divergence of QCF. Matter terms are unimportant in the final stages of the Belinskii *et al.* solution so our conclusion should hold for general distributions of matter and energy.

Although we have quantized only the conformal degree of freedom, the fact that the QCF diverge at the classical singularity is sufficient to demonstrate that quantum uncertainty becomes so large near the classical singular epoch that the classical singularity ceases to have any significance. In analogy with the example of the hydrogen atom can we therefore expect explicit examples of quantum behaviour in the very early Universe? Recent investigations[9,10] have shown that closed Friedmann models have stationaty states and that the Planck length sets the lower limit to the 'size' of the Universe. Whether this is a general feature of quantum cosmology remains to be seen.

Individual electrons detected after the interaction of ionizing radiation with gases

O. H. W. Siegmund, J. L. Culhane, I. M. Mason & P. W. Sanford

Mullard Space Science Laboratory, University College London,
Dorking, Surrey RH5 6NT, UK

The interaction of ionizing radiation (X rays or high-energy particles) with gases results in the creation of electron-ion pairs. For low-energy X rays a small cluster of primary ionization is produced close to the point of the initial photoionization. High-energy particles, however, lose a small fraction of their energy in each of a number of ionizing collisions resulting in a long track composed of clusters of ionization. We report here that the light signals emitted by a parallel-plate proportional counter are fast enough to allow the individual electrons in the ionization clusters to be resolved. By counting the number of electrons for low energy X ray events we demonstrate an improvement in energy resolution of more than a factor of two over conventional proportional counters.

The mean number of electrons, $\bar{n}$, created by the photoelectric absorption of X rays in a gas is a function of the X-ray energy, E, and the mean energy required to create an ion pair, W, such that $\bar{n} = E/W$ (where $W \sim 26$ eV in Ar). In conventional gas proportional counters the electrons produced are accelerated by a strong electric field such that a Townsend charge avalanche results. At a constant mean charge gain, $\bar{A}$, the charge signal from the proportional counter is directly proportional to the X-ray energy. The charge signal pulse amplitude distribution which is observed results from the variation in n and in A. Fano[1] pointed out that the standard deviation in n is $\sigma_n = (F\bar{n})^{1/2}$, where F (the Fano factor) is ~0.17 for Ar. The total fractional deviation in the charge pulse amplitude, $\sigma_N/\bar{N}$, is given by,

$$\frac{\sigma_N}{\bar{N}} = \left[\left(\frac{\sigma_n}{\bar{n}}\right)^2 + \frac{1}{\bar{n}}\left(\frac{\sigma_A}{\bar{A}}\right)^2\right]^{1/2} \qquad (1)$$

where $\bar{N}$ is the mean number of final electron-ion pairs, and

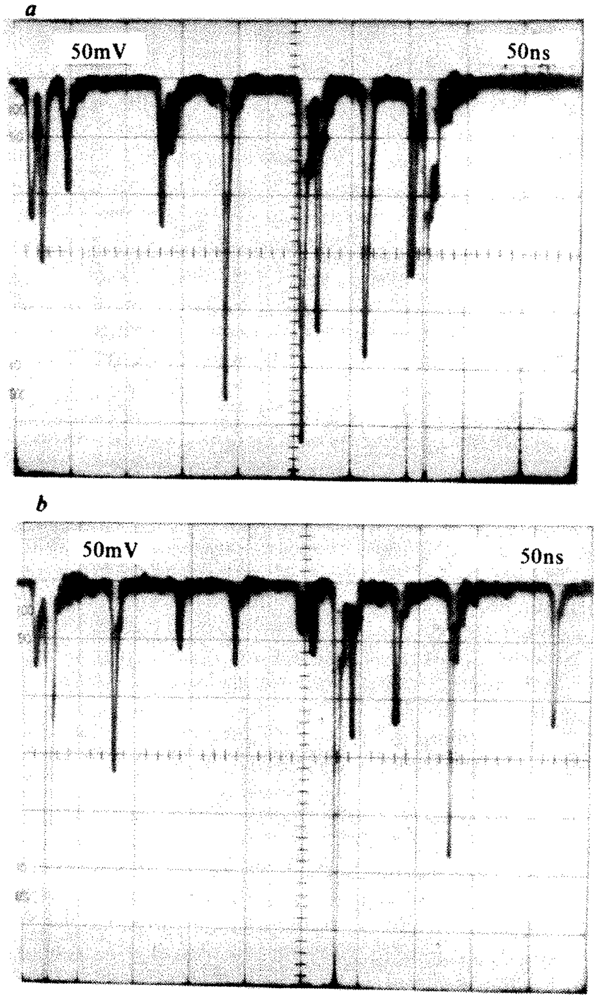

Fig. 1 Traces of the light pulses for two C-K X-ray events. The individual peaks correspond to avalanches initiated by single electrons. The gas used was Ar-CH_4(5%)-CO_2(5%)-N_2(7.5%), with a drift region field strength of ~10 V cm^{-1} and a gas gain of 10^6.

$\sigma_A/\bar{A}$ is the fractional deviation in the charge gain. We may write $f = (\sigma_A/\bar{A})^2$ for the variance in A (f is typically[2] 0.6–0.7 when $A = 10^4$–10^5). Rewriting equation (1) in the form $\sigma_N/\bar{N} = [(F+f)W/E]^{1/2}$, it is clear that the elimination of f would result in a factor of more than two improvement in energy resolution. This is accomplished in the gas scintillation proportional counter[3,4]. The same result may be achieved by counting the individual initial electrons.

In the approach described here the light pulses emitted by Townsend avalanches in a parallel plate proportional counter[5] are detected by a fast photomultiplier tube (PMT, EMI 9818 QBM, ~2 ns rise time). The PMT views the 1 mm-deep avalanche region through an optically transparent anode deposited on a fibre optic substrate[5,6]. The gas mixture used was Ar-CH_4(5%)-CO_2(5%)-N_2(7.5%) at a pressure of 760 torr. Ar and N_2 in the mixture are responsible for the light emission. Ar emits in the range 7,000–8,000 Å and N_2 emits in the range 3,000–4,000 Å (from the second positive band of N_2), with an optimum light emission attained for of the order of 10% N_2 (ref. 6). CH_4 and CO_2 are used in the gas mixture to inhibit secondary electron emission processes, thus enabling high charge gains to be achieved, and to reduce the lateral diffusion of the electron cluster so that acceptable position resolution may be obtained in applications requiring imaging[5,7]. Addition of CO_2 also reduces the electron drift velocity[8] (A. J. F. Den Boggende and C. J. Schrijver, personal communication). Fairly low concentrations (5%) of CH_4 and CO_2 were used as these gases also suppress the light emission[6].

For an X-ray event the overall duration of the light signal is set by the time taken for the initial electron cluster to cross the grid

0028-0836/82/080678—02$01.00

which separates the drift and avalanche regions of the counter. Because each electron initiates an avalanche the overall light signal is composed of a number of light pulses (n). The ability to resolve the light pulses attributable to individual electrons depends on the number of electrons, the overall duration of the light signal and the width of the individual light pulses. As the electron velocities in the avalanche region are high the excitation time, and hence the rise time, of the individual light pulses is fast (~1 ns). It has also been found that the light pulse decay time is fast (~1 ns) because CO_2 and CH_4 heavily quench the excited states responsible for light emission by collisional de-excitation[7]. This time scale compares with a resolution of ~20 ns obtained by Walenta[8] with the charge signal from a time expansion drift chamber. Walenta[8] was able to resolve the ionization clusters for high energy charged particle events, but was not able to resolve individual electrons for 5.9-keV X-ray events, although this might have been possible if low energy (<1 keV) X rays and very low electron drift velocities had been used. Light pulses from a counter of similar geometry to that used in this work were studied by Charpak *et al.*[9] and show some structure for ^{55}Fe events, but the detector gas and operating conditions were not optimized for high time resolution.

In this study the overall duration of the light signal, required to be able to resolve the light pulses initiated individual electrons, was established by using a low field strength (10 V cm^{-1}) in the drift region of the counter, giving a low electron drift velocity ($\sim 1.5 \times 10^5$ cm s^{-1})[7]. However, this field strength is substantially less than that required for optimum position resolution (>100 V cm^{-1})[7] and results in an increase of a factor of ~3 in the lateral size of the electron cluster.

Figure 1 demonstrates the resolution of C–K X rays into several single electron events (the signals were displayed on a Tektronix 1 GHz oscilloscope). It is estimated (from the data in ref. 2) that for the gas mixture used $F \sim 0.17$ and $W \sim 26.5$ eV so the theoretical number of initial electrons is 10.6 ± 1.3. This compares with an experimental value of 11 ± 1.6, deduced by counting the number of light pulses which comprise each individual C–K X-ray event. For C–K X rays this method results in an energy resolution of ~34% FWHM, compared with a value of ~85% FWHM for typical proportional counters. For B–K (0.18 keV) X rays we obtain a value of 7 ± 1.5 electrons compared with a theoretical value of 7 ± 1.1. This gives an experimental energy resolution of ~50% FWHM at B–K compared with ~105% FWHM for conventional counters. The energy resolution for the electron counting technique is compared with the energy resolution of a conventional proportional counter in Fig. 2.

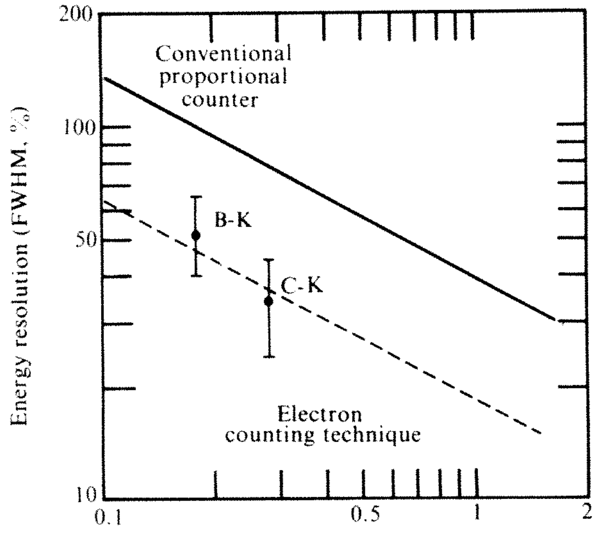

Fig. 2 Comparison of the FWHM energy resolution as a function of X-ray energy for a proportional counter with the predicted energy resolution for counting individual initial electrons, derived from measurements with C–K and B–K X rays.

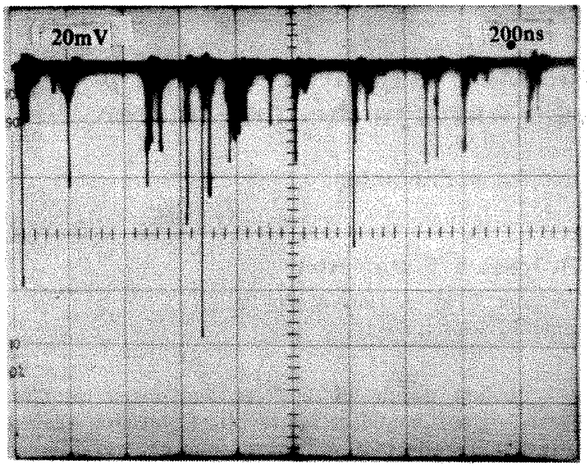

Fig. 3 Trace of the light pulse emitted for a ^{60}Co event showing the resolution into clumps of ionization, which are made up of a number of peaks corresponding to individual electrons.

^{60}Co (~1.2 MeV) γ rays were also observed with the detector. γ rays interact mainly with the walls, resulting in the ejection of high-energy electrons. These electrons are mostly within a factor of two of being minimum ionizing. The ionization tracks produced extend across the 3.5-mm deep drift region of the counter, therefore the overall light signals lasts about four times longer than for X-ray events, which produce small electron clouds. Figure 3 shows the structure of a typical ^{60}Co event in which ionization clusters may be discerned, each composed of several electrons.

In X-ray detection the increased light signal duration for high energy particle events allows identification and rejection of the latter. This ability has already been demonstrated with the integrated light signal[5,6]. Background rejection may be accomplished more efficiently, however, by setting upper limits to the number of single electron avalanches and the duration of the light pulse train.

The practical realization of electron avalanche counting will require suitable pulse counting circuits. Although the theoretical limiting resolution, as determined by the Fano factor, is ~37% (B–K) and ~30% (C–K) it is anticipated that counting errors due to closely spaced single electron events will degrade the resolution achievable in practice. Results obtained with fast logic devices indicate that electronic counting can be at least as efficient as the technique used here. Therefore it seems possible that improvements in energy resolution of at least a factor of two over current proportional counters may be attained.

This improvement in energy resolution for a parallel plate proportional counter should find applications in low energy X-ray astronomy, where both high energy resolution and high spatial resolution are desirable[6]. The ability to count individual electrons, as demonstrated here, makes it possible to determine Fano factors for gases, as was suggested by Walenta[8]. The increased time resolution may also enable improved ionization cluster counting efficiency to be achieved for applications in high-energy charged particle physics.

We thank Professor R. L. F. Boyd for his encouragement. This work was supported by the SERC.

Nonlinear reflectivity of high-power radio waves in the ionosphere

H. Kopka & P. Stubbe

Max-Planck-Institute für Aeronomie, 3411 Katlenburg-Lindau 3, FRG

T. B. Jones & T. Robinson

Department of Physics, University of Leicester,
Leicester LE1 7RH, UK

An important result of earlier ionospheric modification experiments performed at Platteville, Colorado, was the discovery that the reflectivity of the ionosphere was greatly reduced in the reflection region of a high-power radio (pump) wave[1]. Because the reflectivity of low-power diagnostic waves passing through the modified region with frequencies from just below the pump wave frequency up to the F region critical frequency were reduced, the phenomenon was termed wide-band absorption (WBA). Subsequent experimental and theoretical work (for review see ref. 2) has led to the conclusion that WBA is due to the scattering of radio waves from field-aligned irregularities into plasma waves. These irregularities are generated by the interaction of the pump wave and the ionospheric plasma but the mechanism by which this occurs is not completely understood. It is evident, however, that in the process the pump wave itself undergoes WBA. In a recent campaign using the Max-Planck Institute ionospheric modification facility at Ramfjordmoen, near Tromso, Norway, the existence of WBA at high latitudes was confirmed by experiments using low-power diagnostic waves passing through the reflection region of the high-power radio wave[3,4]. As we report here, during an experiment to measure the effect of WBA on the pump wave itself, the essentially nonlinear nature of the interaction between the high-power radio waves and the ionosphere was demonstrated in a new and striking way.

The experiment consisted of measuring the amplitude of the reflected 5.423-MHz pump wave at a receiver about 40 km south of the transmitter while the effective radiated power (ERP) of the pump wave was being changed. The changes in ERP consisted of 40 steps of 6.5-MW increases from 0 to 260 MW (full power) and then 40 incremental decreases of 6.5 MW down to 0 MW, the steps being made at 9-s intervals. One cycle was thus completed within 12 min and was repeated several times.

Figure 1 shows a record of the reflected pump signal during this experiment. The reflected signal increases suddenly during the first step from 0 to 6.5 MW ERP and then continues to increase but less rapidly, during successive increases in ERP. This behaviour is a result of the usual WBA effect and persists up to ~40–50% of full power. However, further increases in power produce a completely new type of behaviour in which the reflected signal decreases with increasing ERP.

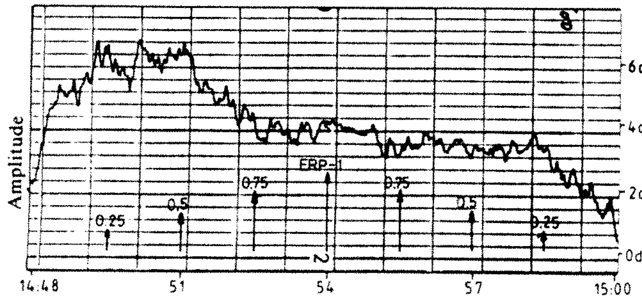

Fig. 1 Record of reflected pump wave amplitude during one 12-min cycle.

This result is a direct consequence of the dependence of the reflectivity of the ionosphere on the amplitude E_0 of the pump wave. If the absorption coefficient of the ionosphere under the influence of the pump wave is $\chi(E_0)$, the reflected amplitude E_R after the wave has travelled twice through a thickness L_0 of modified ionosphere is

$$E_R = E_0\, e^{-2L_0\chi(E_0)} \qquad (1)$$

from which it can be seen that

$$\partial E_R/\partial E_0 = e^{-2L_0\chi(E_0)}\,(1 - 2L_0E_0\partial\chi/\partial E_0) \qquad (2)$$

Thus, as long as χ is an increasing function of E_0 (which theory predicts to be the case), then expression (2) shows that E_R will increase with E_0 when E_0 is less than a critical value, E_c, but that E_R will decrease with increasing E_0 when E_0 exceeds E_c, where E_c is given by

$$E_c = 1/(2L_0\partial\chi/\partial E_0) \qquad (3)$$

This result may have far-reaching practical implications, especially in the field of telecommunications. It is normally assumed that in a broadcasting system, the signal amplitude at a remote receiver can be increased by increasing the radiated power of the transmitter. The present results suggest that a certain optimum power exists above which the signal received via the ionosphere at a remote site will be reduced.

Unusual luminescence behaviour of terbium phosphate glasses

David J. Cronin, Douglas H. Blackburn & Wolfgang K. Haller

National Bureau of Standards, Washington, DC 20234, USA

While preparing a terbium-containing phosphate glass, an intense emission of green light was observed when the melt was poured into a metal mould. This emission was easily visible to the naked eye and was only observed on quenching of the melts. To our knowledge this phenomenon, termed 'cooling-induced luminescence (CIL)', has not previously been reported. Experimental evidence suggests that the CIL may be related to a thermally induced shift in the oxidation-reduction balance in the melt. A similar phenomenon was also observed with europium phosphate melts.

To determine the exact nature of the emission, a series of spectra was recorded using a quartz prism spectrometer, taking successive photographic film exposures, as the melt cooled. Figure 1 shows the emission spectra obtained during the cooling of a melt of terbium metaphosphate, $Tb(PO_3)_3$, and the emission spectrum obtained by exciting the glass, at room temperature, with an UV light source fitted with a 'black light' filter. The CIL peaks agree well with the UV-excited peaks and correspond to the known fluorescence spectrum of Tb^{3+}. The peaks at 412 and 436 nm in the spectrum taken at 1,284 °C also correspond to known terbium emissive transitions, even though they were not observed in the UV-excited spectra. The spectra in Fig. 1 obviously represent a superposition of the terbium fluorescence lines and the thermal emission continuum of the hot melt. Figure 2 shows the thermal emission continuum of a metaphosphate melt, $La(PO_3)_3$, which does not contain an ion exhibiting fluorescence.

Quenching of the melt was required to observe CIL. Table 1 summarizes the effect of cooling history and rate for $Tb(PO_3)_3$. If

0028–0836/82/080680—03$01.00

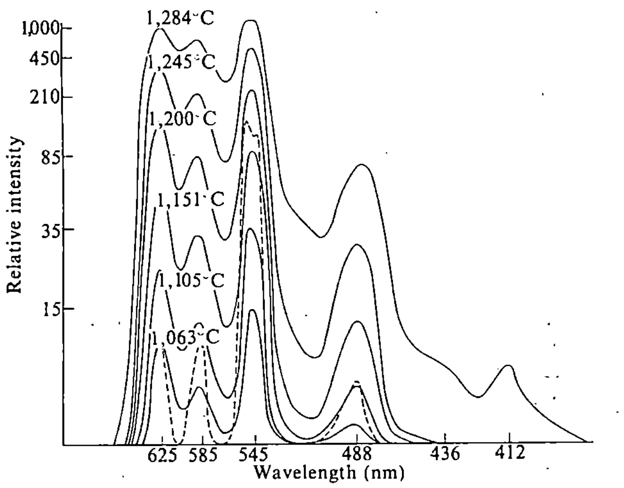

Fig. 1 Spectra obtained on cooling of $Tb(PO_3)_3$. ---, UV-excited spectrum of $Tb(PO_3)_3$.

the melt was allowed to cool freely in air in its crucible, a cooling rate of ≤ 2 °C s^{-1}, no emission was observed. On casting from an initial melt temperature of 1,400 °C, the centre temperature of the cast piece showed a cooling rate of ~10 °C s^{-1} and the emission for a 100 g melt was visible for ~20 s. In another set of experiments small solid glass samples were heated to up to 1,100 °C and then quenched. If the samples were allowed to cool in air the initial cooling rate was ~100 °C s^{-1} but no CIL was observed. However, if the samples were taken from the heat source and immediately placed in water, giving an initial cooling rate of ~500 °C s^{-1}, CIL was observed for samples having an initial temperature of 850 °C or higher. No CIL was observed in cases where the initial temperature was <850 °C. These results indicate that a certain quench rate is needed to observe CIL and that this quench rate is related to the initial temperature of the glass.

Several melts were made by melting a mixture of Tb_4O_7 and $NH_4H_2PO_4$ to determine the composition range over which the CIL effect could be observed. Additions, if any, were in the form of oxides, except in the case of sodium where the carbonate was used. The melts were carried out at 1,400 °C in Al_2O_3 crucibles after an initial preheating to drive off most of the NH_3 and H_2O and preheat the crucible before placing it in the melt furnace. The melts were generally cast after 1 h at the melting temperature.

In binary terbium phosphates, CIL was observed over a composition range of 16–25 mol % Tb_2O_3. No melts were made with >25 mol % Tb_2O_3. Various oxides were added to the $Tb(PO_3)_3$ composition, at 5 mol %, to determine their effect on the CIL. Individual additions of MgO, Na_2O, and Al_2O_3 did not seriously affect the emissions. However, additions of oxides with variable valency states, such as Sb_2O_3 or CeO_2, completely quenched the CIL effect, although UV-excited fluorescence was observed.

As an alternative to introducing the P_2O_5 as $NH_4H_2PO_4$, other melts were prepared from material formed by mixing H_3PO_4 and Tb nitrate solution. The terbium nitrate was made by digesting terbium oxide in concentrated nitric acid. The material was dried at ~100 °C before placing it in the melt crucible. Melting was carried out in an Al_2O_3 crucible at 1,400 °C for 1 h, as with the other melts, and resulted in a clear fluid melt which cooled to a clear glass. Although it showed only a very faint indication of CIL on pouring, UV-excited fluorescence was observed.

Table 1 Effect of thermal history on CIL in $Tb(PO_3)_3$

Initial temperature (°C)	Cooling rate (°C s^{-1}) CIL observed	CIL not observed
1,400	10	2.5
1,100–850	500	100
$\leq$800	—	500

The intensity of the CIL in these melts could be increased greatly, to the level of the original glasses, by bubbling NH_3 or CO gas through the melts at 1,400 °C. The CIL could be quenched again by bubbling O_2 gas through the melt.

During melting of the various compositions, it was noted that holding time at temperature also affected the CIL. The Na_2O-containing glass, which originally exhibited CIL, did not show CIL after an additional 3 h of melting. The Al_2O_3-containing glass also showed a significant decrease in intensity of the CIL in similar conditions, as did $Tb(PO_3)_3$, particularly at long melting times, up to 22 h. The ability of oxygen to quench the CIL indicates that the decrease in intensity may be due to the slow oxidation of the melt from prolonged heating in air.

CIL was also photographically recorded for a europium metaphosphate melt, though the luminescence is in the red portion of the spectrum and therefore difficult to distinguish visually from the black body radiation.

Our results identify the emissions involved in the CIL as the normal Tb^{3+} fluorescence transitions, and provide some indication of the nature of the excitation process. One obvious possibility is excitation by the thermal black-body radiation. However, if the mechanism was a simple excitation by the UV portion of the continuum, a steady-state emission would be expected while holding the glass at elevated temperatures, and none is observed. Another possibility is a stress-induced triboluminnescence. However, the CIL occurs at temperatures where the melt is still quite fluid and no stress could be developed.

The need for quenching to observe the CIL, and the dependency of high quench rates on starting temperature, indicate that the emission is the result of the decay of a temperature-dependent excited state. The fact that the cooling rate necessary to observe the CIL depends on starting temperature may indicate that the decay process is always radiative but during slow cooling the emission cannot be observed because of the relative magnitude of the background. The other possibility is a competition between radiative and nonradiative decay with the radiative process being favoured in rapid cooling conditions and the nonradiative process in slow cooling conditions.

One possible temperature-dependent mechanism is a valency change of the terbium. Only terbium oxide is known to show a large change in Tb^{4+}/Tb^{3+} ratio as a function of temperature[1], and many other multivalent ions, such as iron[2] and cerium[3], show similar changes even when incorporated in a glassy matrix. That oxidation of the melt, by batch additions (such as Sb_2O_3, CeO_2) or by bubbling O_2 gas, quenches the CIL and reduction of the melt, by CO_2 or NH_3 gas, can revitalize the CIL indicates the sensitivity of the effect to the overall redox balance of the

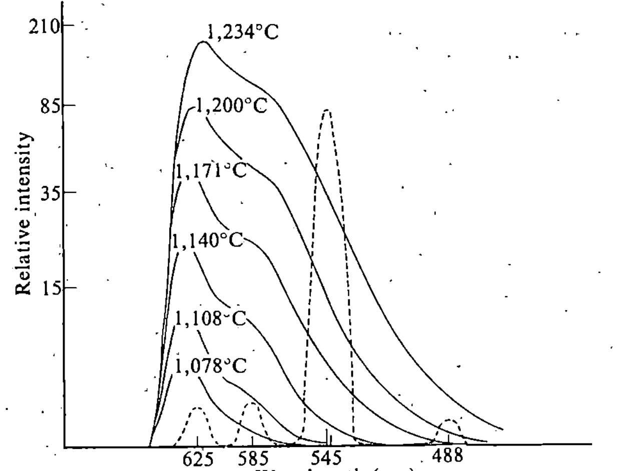

Fig. 2 Spectra obtained on cooling of $La(PO_3)_3$. ---, UV-excited spectrum of $Tb(PO_3)_3$.

system. Therefore a temperature-dependent valency change may indeed contribute to the CIL effect. However, the intensity of the Tb^{3+} fluorescence in UV irradiation was essentially the same, for terbium phosphate glasses, regardless of whether CIL was observed or not, implying that the Tb^{3+} content of the glasses, at room temperature, was not greatly different, thus indicating that the redox changes are more complicated than a simple shift in Tb^{4+}/Tb^{3+} ratio. It also is not clear from our results whether the quenching of the CIL by oxidation prevents formation of the excited state or shifts the decay process to a non-radiative path.

In conclusion, a unique form of luminescence was observed which was quite sensitive to the overall oxidation reduction balance of the melt and the rate of cooling of the melt. The experimental evidence indicates that the excitation mechanism requires species of a particular valence and may be due to a thermally induced shift in the oxidation reduction balance in the melt which results in the observed terbium luminescence. This may involve the terbium directly or may involve the phosphorus with the energy released being transferred to the terbium to produce the fluorescence.

Slope anomaly in the vapour pressure curve of Hg

S. R. Hubbard

Lowestoft College of Further Education, St Peters Street,
Lowestoft NR32 2NB, UK

R. G. Ross

School of Mathematics and Physics, University of East Anglia,
Norwich NR4 7TJ, UK

The investigation of normally-metallic fluids at reduced densities has created considerable experimental and theoretical interest. Hensel[1] has presented evidence for transitions, related to electronic properties, in both the liquid and vapour phases of Hg, and predicted that these would affect the liquid–vapour transition. We present here evidence that the vapour pressure curve of Hg, $p(T)$, has an unusual and probably unique form in that the $\ln p$ against $1/T$ plot showed a sharp change of slope at temperature $T = T' = 1{,}361$ K and saturated liquid density $\rho_L = 10.7\ \mathrm{g\,cm^{-3}}$. The latter is about the density at which Hensel[1] deduced that the electronic mean free path equalled the mean interatomic spacing, and which he took to be associated with the electronic-property related transition in the liquid phase.

Our experiments were made using an internally-heated pressure vessel pressurized with argon gas. The sample of Hg was contained in a closed cell, fabricated largely of Mo, which entered the internal furnace of the pressure vessel and which was also connected by means of high-pressure capillary tubing to a strain gauge type of pressure transducer outside of the pressure vessel. This transducer was used to measure the vapour pressure. The argon pressure in the pressure vessel was adjusted so as to be approximately equal to the measured vapour pressure of the Hg to prevent deformation of the cell under stress. The pressure transducer was calibrated using a dead-weight tester, and we estimate the inaccuracy in p as ±0.4 MPa. The temperature was measured using several Pt/Pt13Rh thermocouples in close contact with the hot part of the cell where the liquid–vapour meniscus was located. Users of internally-heated pressure vessels are familiar with systematic errors in temperature measurement arising from convection in the pressure-transmitting medium, here argon gas. To correct for such error, we adjusted our temperatures so that, at 929 K, our data agreed with the relatively accurate, low-temperature vapour pressure data of Sugawara *et al.*[2]. The required adjustment of temperature varied from 0 to 20 K in the various runs which were made.

We fitted our data to several different equations using a least-squares procedure. The simplest form of equation was $\ln p = A/T + B$. To obtain a good fit to our data, we needed different values of A and B above and below a temperature of 1,361 K where we observed a change of slope (Fig. 1). At low temperatures, our data in the range 742–1,271 K yielded

$$\ln (p/\mathrm{MPa}) = -7{,}148(\mathrm{K}/T) + 9.064 \qquad (1)$$

Using the same procedure, the data of Sugawara *et al.*[2] in the temperature range 602–929 K yielded

$$\ln (p/\mathrm{MPa}) = -7{,}132(\mathrm{K}/T) + 9.038 \qquad (2)$$

From the agreement of the corresponding parameters in equations (1) and (2), in particular that corresponding to the slope, we inferred that systematic error in temperature measurement in our experiments was constant, essentially independent of temperature, in any given run. Over the temperature range 742–929 K, where there was data overlap between our experiments and those of Sugawara *et al.*[2], pressures calculated using equations (1) and (2) differed at most by 0.88%.

The same fitting procedure and form of equation when applied to our data in the temperature range 1,389–1,719 K yielded

$$\ln (p/\mathrm{MPa}) = -8{,}180(\mathrm{K}/T) + 9.822 \qquad (3)$$

To confirm the validity of our data at the higher temperatures, we used the most recent and reliable values of critical temperature, T_c, and critical pressure, p_c, obtained independently

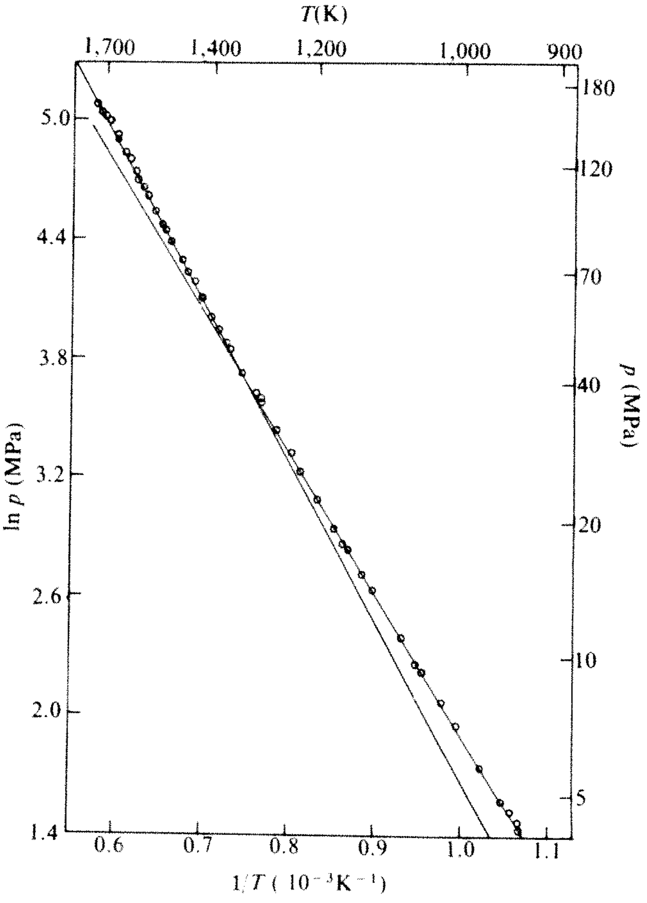

Fig. 1 Vapour pressure of Hg.

0028-0836/82/080682—02$01.00

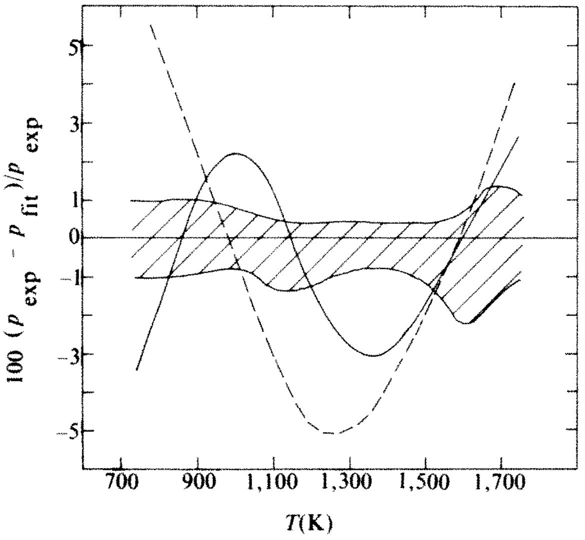

Fig. 2 Deviation between experimental and fitted values for vapour pressure of Hg: solid line, $\ln p = A/T + B + C \ln T$; broken line, $\ln p = A/T + B$; cross-hatched region, deviations scattered within this region both for Frost–Kalkwarf[6] equation $\ln p = A/T + B + C \ln T + Dp/T^2$, and for equations (1) and (3) of the present work.

by other workers. Experiments by Neale and Cusack[3] and Schönherr and Hensel[4] yielded an experimental value $p_c = 170$ MPa, obtained by averaging 167.5 and 172 MPa. Substitution in equation (3) of values of T_c obtained by these workers yielded an average predicted value $p_c = 179$ MPa, that is, 9 MPa higher. Alternatively, substitution of the same values of T_c in equation (1) yielded an average predicted value $p_c = 151$ MPa, that is, 19 MPa lower than the average experimental value obtained independently. From such comparisons we inferred: (1) that our predicted value of p_c from equation (3) was in reasonable agreement with other work, (2) that our values of vapour pressure near p_c were not subject to serious unsuspected systematic error and (3) that linear extrapolation of low temperature data in a $\ln p$ against $1/T$ plot (equation (1)) yielded an improbably low predicted value of p_c. As we have found reasonable agreement of our data with that of other workers[3,4] at $T = T_c$, and good agreement of the slope with the data of Sugawara *et al.*[2] at low temperatures, it follows that the $\ln p$ against $1/T$ plot must bend upward at intermediate temperatures.

The typical results shown in Fig. 1 were reproducible both on heating and cooling and for a range of different total Hg masses in the cell. The temperature at which the change of slope occurred (T') we estimated as 1,361 ± 30 K.

We also attempted to fit other forms of equation to our data; the results are shown in Fig. 2. A single equation of form $\ln p = A/T + B$, or the Kirchhoff equation $\ln p = A/T + B + C \ln T$, evidently yielded poor fits. The latter has been used successfully[5] to fit high-temperature vapour pressure data for Cs, which showed only a slight curvature in a $\ln p$ against $1/T$ plot, concave towards the $1/T$ axis. The four-parameter implicit equation, $\ln p = A/T + B + C \ln T + Dp/T^2$, due to Frost and Kalkwarf[6], gave as good a fit as two equations of form $\ln p = A/T + B$, and thus these two possibilities cannot be distinguished on numerical grounds.

Whatever the form of equation(s) used, the data shown in Fig. 1 clearly indicate a rapid change of slope at a temperature ~1,361 K. As already suggested by Hensel[1], liquid–vapour equilibrium would be expected to be affected by an electronic 'transition' in the liquid phase or vapour phase, or both. By using our value for T' together with well-established coexistence curve data[7], we obtained a value $\rho_L = 10.7 \pm 0.3\ \mathrm{g\,cm^{-3}}$ for the corresponding liquid phase density. This is about the density which has been taken[1,8] to be that by which the electron mean free path has been reduced to about the mean interatomic spacing, and which marks the beginning of a rapid reduction in the density of states at the Fermi level ($N(E_F)$) for lower densities. The latter densities have been referred to as corresponding to the strong scattering region. As the density of states should affect the thermodynamic properties, we conclude that the reduction of $N(E_F)$ with volumetric expansion of the liquid phase in the strong scattering region is the most likely cause of the different slope of the vapour pressure curve which we have found for temperatures greater than 1,361 K.

Factors controlling the acidity of natural rainwater

R. J. Charlson* & H. Rodhe

Department of Meteorology, University of Stockholm, Arrhenius Laboratory, S-106 91 Stockholm, Sweden

It is often assumed[1–4] that the *p*H of natural rainwater is controlled by the dissociation of dissolved CO_2, has a value of 5.6, and that decreases below this are due to the addition of acidic components by human activity. However, decreases could be due to the removal by rainwater of naturally occurring acids from the air (notably H_2SO_4 in the natural portion of the sulphur cycle). Consideration of the cycling of water and sulphate through the atmosphere and the amount and composition of sulphate aerosol expected to be scavenged by a given amount of cloud water in remote locations indicates that, in the absence of basic materials (such as NH_3 and $CaCO_3$), average *p*H values of ~5 are expected to occur in pristine locations. This value must vary considerably due to variability in scavenging efficiencies as well as geographical patchiness of the sulphur, nitrogen and water cycles. Thus, *p*H values might range from 4.5 to 5.6 due to variability of the sulphur cycle alone. Because of widespread concern regarding the acidification of rain, it is important to understand the factors controlling the *p*H and composition of natural rainwater. We suggest here that there are integral constraints imposed by (1) the requirement for mass continuity in each elemental cycle and (2) the relative concentrations of soluble species and liquid water in cloudy air; these factors must be mutually consistent.

Although the NH_3/NH_4^+ part of the nitrogen cycle is important (NH_3 being the dominant atmospheric gaseous base) it is not yet possible to consider it quantitatively. Similarly, the $NO/NO_2/HNO_3$ cycle is inadequately measured. However, HNO_3 will always add to the acidity of rainwater due to H_2SO_4. We can make a preliminary estimate of the concentrations of strong acids in rain in remote locations by first studying the sulphur cycle alone. The maximum or potential acidity thus estimated neglects neutralization by bases such as NH_3 or $CaCO_3$ which will increase *p*H. However, as both NH_3 and basic dust concentrations are often low (such as in maritime air) this approach has actual application.

Estimates of the natural flux of sulphur through the atmosphere have been based on indirect arguments: for example, using river run-off data[5], and more direct measurements of deposition by precipitation[6], of emissions of sulphur-containing gases from the ocean surface[7], coastal sediments[8], or volcanoes[9]. The global total of such fluxes—disregarding anthropogenic emissions and those associated with the formation of sea spray—is still uncertain but recent estimates[6,10] are in the range $35-110\times10^{12}$ g S yr^{-1}, which is comparable with the present anthropogenic emissions[11] of $\sim100\times10^{12}$ g yr^{-1}. For illustrative purposes we may assume a value of 60×10^{12} g yr^{-1} for the global emission of natural, non-sea spray sulphur, but it is uncertain by at least a factor of two in either direction. If this sulphur were evenly distributed over the globe and one-half of it were deposited as sulphate in precipitation[12], the resulting pH would be ~5.2 (assuming the remaining sulphur is present as H_2SO_4 in the rainwater).

Note that the 'global sulphur cycle' is far from global. Because of the limited residence time in the atmosphere of the major sulphur-bearing compounds (H_2S, $(CH_3)_2S$, SO_2 and SO_4^{2-})[12] and an uneven geographical and temporal distribution of sources and sinks, the sulphur cycle will exhibit large variations in space and time. Examples include volcanic emissions of SO_2; production of $(CH_3)_2S$ in the surface water of the oceans and its subsequent release to the atmosphere that is likely to be coupled to the biological productivity of the ocean water and therefore vary with it; and the possibility of enhanced sulphur emissions in coastal areas (see, for example, ref. 13). (OCS, while important in terms of concentration, is assumed to be less important in this context due to a smaller flux.) Consequently, the global averages need not be very representative for any particular location. As a first step towards examining the factors controlling this variability, the cycle can be evaluated over spatial scales compatible with the average residence time in the atmosphere of the important sulphur compounds, that is, a few hundred to a few thousand kilometres[14]. Studies of regional sulphur budgets have already been attempted for regions with very large industrial emissions[15,16].

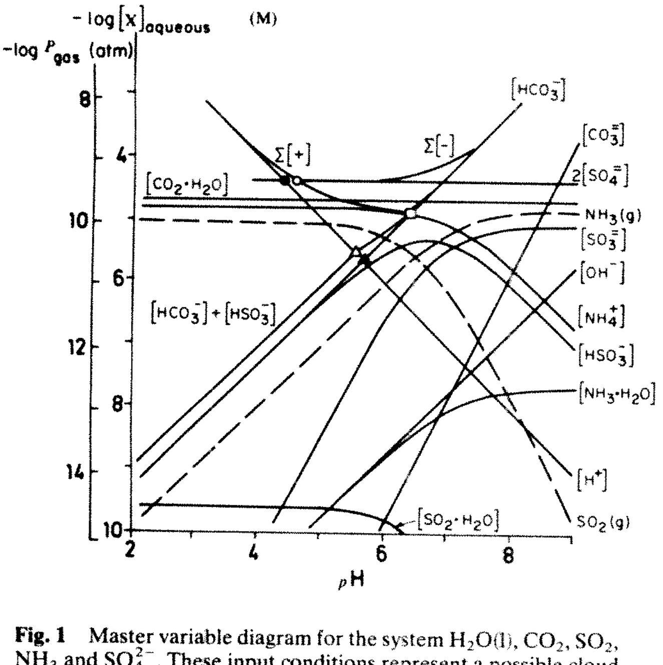

Fig. 1 Master variable diagram for the system H_2O(l), CO_2, SO_2, NH_3 and SO_4^{2-}. These input conditions represent a possible cloud in a remote, unpolluted area. Assumptions: $T=5$ °C; $L=0.5$ g m^{-3} liquid cloud water; $CO_2=340$ p.p.m.v.; $SO_2=100$ p.p.t.v.; $(NH_3+NH_4^+)=0.13$ μg m^{-3} as NH_3; $(SO_4^{2-})_{aerosol}=1.0$ μg m^{-3}, all dissolved in cloud. Charge balances: ○, pH 4.6 for whole system; ●, pH 4.4 in absence of NH_3 (and NH_4^+); □, pH 6.2 in absence of SO_4^{2-}; △, pH 5.5 in absence of both NH_3 and SO_4^{2-}; ▲, pH 5.6 in absence of NH_3, SO_4^{2-} and SO_2. [X] denotes aqueous concentration (M). SO_2(g) and NH_3(g) represent the gas phase (----). Equations and equilibrium constants have been taken from refs 17, 35.

Table 1 Potential acidity (pH) of atmospheric liquid water: effects of dissolved aerosol SO_4^{2-} and liquid water content of cloud

SO_4^{2-}	L (g m^{-3})		
(μg m^{-3})	0.1	0.5	2.5
0.04	5.1	5.4	5.5
0.2	4.4	5.1	5.4
1.0	3.7	4.4	5.1

Concentrations of CO_2 and SO_2 are assumed to be constant and equal to 340 p.p.m.v. and 100 p.p.t.v. respectively. Total $NH_3=0$.

We conclude that substantial variations around the global average value of the potential acidity attributable to naturally circulating sulphur should be expected. The absolute magnitude of such variations is hard to estimate without a better understanding of the characteristics of the regional sulphur cycles, but variation by a factor of five either way seems possible. The corresponding pH values would then lie in the range 4.5–5.6. If the natural part of the atmospheric sulphur cycle is not spatially uniform by even a factor of two, then the pH of rainwater unaffected by human activity could be <5.0 in some regions. (Note that the concentration of hydrogen ion in rainwater will be influenced by other compounds as well; for example, the NH_3/NH_4^+ cycle may be as variable as the sulphur cycle, and probably not in phase with it.)

Another approach to estimating the composition of rainwater is to utilize existing data on aerosol composition and liquid water content of clouds. Although the degree to which the composition thus calculated may reflect that of rain itself is not known precisely, the composition of rainwater, cloud water and the aerosol and trace gases that went into the cloud must be related.

Equilibria exist in clouds among several trace gases, their respective dissolved species and liquid water, and there are further inputs of aerosols containing sulphates, soil-derived dust and sea salt to cloud droplets. The sulphate aerosols are of particular interest because they often occur as H_2SO_4 partly neutralized by NH_3 (ref. 17). An approximate empirical formula of NH_4HSO_4 exists in remote, maritime submicrometre aerosols[18] and, as such particles can be incorporated into cloud droplets, sulphate aerosols are potentially important sources of strong acid in rain. If we neglect the soil dust and sea salt, given the 3 Henry's law expressions for NH_3, SO_2 and CO_2, 6 equilibria for dissociation of these and water, 3 mass conservation equations for NH_3 and NH_4^+, S(IV) and carbonate species and one equation of charge balance, a system of 13 equations can be solved for the equilibrium conditions[17]. Figure 1 is a Sillén or master variable diagram[19] for the system NH_3, SO_2, CO_2, H_2SO_4 and H_2O(l) in a pristine cloud, in which the concentration of each dissolved species and the partial pressure of the trace gases are given as functions of pH. When the 9 equilibrium statements are combined with the conservation equations, 12 separate curves result, portraying the concentration of each of the species. In addition, $[SO_4^{2-}]$ is given as pH independent at $p\text{H}>3$, while CO_2(g) is omitted and the sum of $[HSO_3^-]+[HCO_3^-]$ is included. The charge balance then is given at the pH where the sums of positive and of negative charges are equal ($\Sigma[+]=\Sigma[-]$). For this set of conditions (see Fig. 1 legend), at $p\text{H}=4.6$ there is charge neutrality (open circle in Fig. 1) and sulphate is the dominant anion; $[NH_4^+]$ is slightly $<[H^+]$, $[HCO_3^-]\cong[HSO_3^-]\cong10^{-6.8}$ and $\ll[SO_4^{2-}]$. Also, the partial pressure scale is set so that the curves for SO_2(g) and NH_3(g) have the same limiting ordinate value as $[SO_3^{2-}]$ and $[NH_4^+]$ respectively. Thus the mass continuity expressions for these two can also be followed graphically as functions of pH, showing that if $p\text{H}<5.5$, most S(IV) is SO_2(g) while NH_4^+ is the dominant ammonia species.

This plot can also be used to show what equilibrium pH would occur in the absence of various components. Only in the absence of NH_3, SO_2 and SO_4^{2-} does pH equal 5.6; higher values occur with the absence of SO_4^{2-} alone, while pH decreases if NH_3 is removed. Increasing CO_2 slightly decreases the pH in those cases where SO_4^{2-} is low. (Doubling CO_2 causes at most a decrease in pH of 0.15.) Decreasing SO_4^{2-} or increasing NH_4^+ by even small amounts increases the pH significantly. Complete oxidation of all the SO_2 in the cloud would raise $[SO_4^{2-}]$ to 2.8×10^{-5} M and decrease the equilibrium pH to 4.4, with all other variables constant. Thus, although these input conditions were selected as possible in a remote, unpolluted area, they are clearly variables to which pH is very sensitive.

To study further the relationship between the chemical compositions of aerosols, cloud water and rainwater and to estimate the effect of their variability on pH, consider the simplest case of in-cloud scavenging of a pre-existing sulphate aerosol with no in-cloud SO_2 oxidation. The cloud water composition is then given by[20]

$$[SO_4^{2-}]_{\mathrm{cloud}} = \frac{\varepsilon(SO_4^{2-})_{\mathrm{aerosol}}}{96L} \qquad (1)$$

where $[SO_4^{2-}]$ cloud is the molar sulphate concentration in cloud water, 96 is the molecular mass of SO_4^{2-}, $(SO_4^{2-})_{\mathrm{aerosol}}$ is the mass concentration of sulphate aerosol in air ($\mathrm{g\,m^{-3}}$), ε is the scavenging efficiency for sulphate aerosol particles in the cloud and L is the liquid water content ($\mathrm{l\,m^{-3}}$) of the cloud. For soluble particles of 0.1–1.0 μm radius, ε is expected to be[20] 0.5–1.0.

Allowing for dilution (D) and evaporation (E) of the cloud and rainwater, the sulphate concentration in rainwater becomes:

$$[SO_4^{2-}]_{\mathrm{rain}} = (SO_4^{2-})_{\mathrm{aerosol}}\frac{\varepsilon DE}{96L} \qquad (2)$$

Data from the OECD study on long-range transport of air pollutants[21] indicate a value of $\varepsilon DE/L$ in the range $(0.6\text{–}1.6)\times 10^3\ \mathrm{m^3\,kg^{-1}}$. If ε, D and E were unity, this would correspond to a liquid water content of $\sim 1\ \mathrm{g\,m^{-3}}$, a value which is reasonable compared with observations of the liquid water content of precipitating clouds[22] and consistent with other published values of washout ratios[23,24].

Table 1 lists values of expected pH of rain as a function of $(SO_4^{2-})_{\mathrm{aerosol}}$ and L for $\varepsilon\times D\times E=1$. The effects on pH of compounds other than CO_2 and a background concentration of SO_2 of 100 p.p.t.v. (parts per 10^{12} by vol.)[25] are disregarded. For simplicity, SO_2 is assumed not to react. The L values used embrace most measured values of the liquid water content of clouds[22]. Generally, the lower values may be more representative of fogs and stratiform clouds[26] and the higher values of convective clouds, especially the rain-producing ones. Data from remote locations on the concentration of aerosol sulphate (excluding the contribution from sea spray) are sparse but values vary from $\sim 0.05\ \mu\mathrm{g}\ SO_4^{2-}\ \mathrm{m^{-3}}$ in remote parts of South America[27] to of the order of $1\ \mu\mathrm{g}\ SO_4^{2-}\ \mathrm{m^{-3}}$ in the marine boundary layer[28,29]. The range of sulphate values used in the Table evidently covers most of the observed data. Although it might have been logical to vary SO_2 with the concentrations of sulphate, dissolved SO_2 itself only slightly affects pH (see Fig. 1), and we did not want to complicate the picture with further variations. Clearly a raining cloud low in both basic materials and L might be quite acidic. It is not possible to construct a frequency-of-occurrence histogram from these computations, the above discussion indicates that pH values well below 5 might occur in pristine areas.

Considerable spatial and temporal variations in the acidity should be expected with lowest pH values occurring in situations with high concentrations of non-sea spray sulphate in aerosols, low concentrations of basic constituents (such as ammonia gas, $CaCO_3$) and low liquid water content in the clouds. As the sources of these basic constituents are mainly in continental areas whereas substantial emissions of sulphur compounds take place over the oceans, rain is likely to be more acidic in marine environments than over the continents. It is therefore not appropriate to use $p\mathrm{H}=5.6$ as a reference value against which human influences should be judged. We believe that, generally, pH alone is a poor indicator of departure from the natural composition of rain and cloud water, mainly because of its large natural variability and the difficulty of measuring it accurately.

To assess man-made acidification it is necessary to study in detail the cycles—particularly of sulphur and nitrogen—that influence the acidity of atmospheric water, in different regions of the world, and the degree to which the cycles have been affected. Long-term (decades) programmes for monitoring the chemical composition of air and precipitation should be supplemented by direct estimates of emission fluxes from different types of sources potentially affecting the monitoring sites. A large number of variables must be studied simultaneously to define clearly natural and perturbed conditions.

Note that the present pH values in precipitation in the heavily industrialized regions are significantly affected by anthropogenic emissions. In Northern Europe and eastern parts of North America[4,30,31], annual average pH values of 4.3 are common. At a typical station in rural parts of southern Sweden (Forshult; lat. 60.15 N long. 13.78 E) 50% of the monthly precipitation samples during the period 1975 to 1980 had a pH value in the range 4.1–4.6, due primarily to H_2SO_4 and secondarily to HNO_3 (ref. 32). Annual sulphur deposition as SO_4^{2-} is typically 2–3 $\mathrm{g\,m^{-2}}$, resulting in substantial ecological effects[31]. Clearly the sulphur and nitrogen cycles in these regions are much perturbed[15,21] and if all industrial emissions of SO_2 and NO_x were stopped—emissions of NH_3 remaining the same—the pH would increase to >5. Note that low pH values reported for rainwater in remote locations[33,34] need not be interpreted as due exclusively by natural processes. The possibility of long-range as well as local anthropogenic influences should be investigated. However, natural factors exist which can cause variable and significant decreases of pH from that expected from pure carbonic acid equilibrium.

Mesozoic magnetic anomalies in the southern Natal Valley

S. W. Goodlad*, A. K. Martin* & C. J. H. Hartnady†

* Marine Geoscience Unit and † Precambrian Research Unit,
Department of Geology, University of Cape Town, Rondebosch,
South Africa

The recognition of Mesozoic magnetic anomalies M0–M12 within the submarine Natal Valley (south-west Indian Ocean) provides a further constraint on the relative motion between South America (Falkland Plateau) and Africa during the early opening phase of West Gondwanaland (Fig. 1). Colinear with M12, magnetic anomaly *G* (ref. 1) is delineated north of the South Tugela Ridge[2], an acoustic basement high which is suspected to have been emplaced within continental crust immediately north of the continental–oceanic crust boundary (COB) during the initial rifting phase. Starting from a revised West Gondwana reconstruction[3] and using palaeo-poles of rotation[1,3], the Falkland Plateau can be rotated into the Natal Valley superposing the corresponding Georgia Basin and Natal Valley magnetic anomalies. This achieves an optimum continuity of inter-continental structural lineaments[3] by overlapping of an anomaly intermediate to M10 and M11 (~M10N[4]). This suggests that the Natal Valley COB is located between anomalies M10 and M11, implying that in this zone of south-west Gondwana, seafloor spreading commenced at ~125 Myr.

Previous confirmation of the continental nature of the Falkland Plateau[5-7], necessitates its inclusion in recent reconstructions of south-west Gondwana[3,7,8]. In these reconstructions it fits into the gap between south-east Africa and the Mozambique Ridge (Fig. 1). During the West Gondwana drift phase, the Falkland Plateau moved past Africa constrained by the orientation of the Agulhas/Falkland Fracture Zone[9,10]. Recognition of magnetic anomalies on conjugate margins of the southern South Atlantic has helped to define the seafloor spreading history of South America and Africa[1] north of the Agulhas/Falkland Fracture Zone. In contrast, to the south of this fracture zone, the Natal Valley has been largely ignored as a prospective source of geophysical data for testing reconstruction of West Gondwana. The distant location (~40°) from the early pole of rotation[1,3] suggests that seafloor spreading in the Natal Valley may have advanced at a fast rate and thus resultant magnetic anomalies should be widely spaced and easy to recognize. Magnetic anomaly lineations present in the Natal Valley should be aligned approximately perpendicular to the Agulhas Fracture Zone.

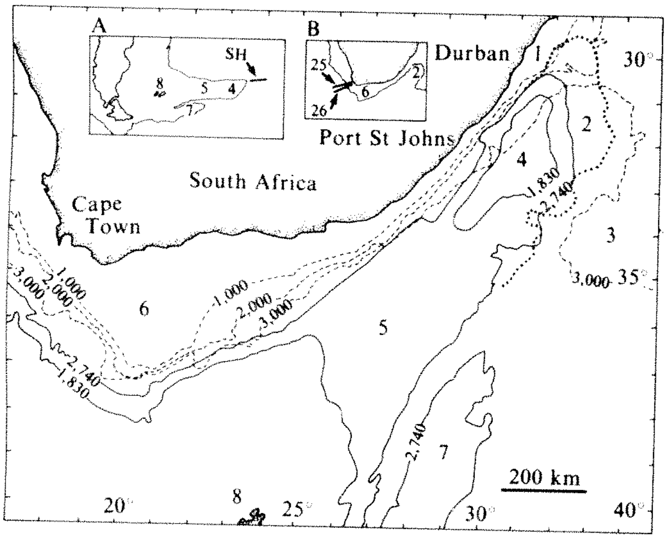

Fig. 1 Reconstruction of south-west Gondwana after Martin *et al.*[3] depicting the close contiguity of the Falkland Plateau and Natal Valley physiographic features. Dashed line, South African bathymetry[2,17] (1,000, 2,000 and 3,000 m). Solid line, South American/Falkland Plateau bathymetry[18] (1,830 and 2,740 m); conversion factor 1 fathom = 1.83 m. Alternative position for north-east apex of the Falkland Plateau (2,740 m isobath) in reconstruction using Rabinowitz and LaBrecque[1] rotation parameters dotted. Physiographic zones: 1, Tugela Cone; 2, Natal Valley; 3, Mozambique Ridge; 4, Maurice Ewing Bank; 5, Falkland Plateau Basin; 6, Agulhas Bank (Outeniqua Basin); 7, Burdwood Bank; 8, Falkland Islands. A, The location of magnetic profile Shackleton[11] (SH) in the Georgia Basin east of the Falkland Plateau apex. B, Locations of magnetic profiles 25 and 26 (ref. 1) from the Cape Basin, south-west of South Africa.

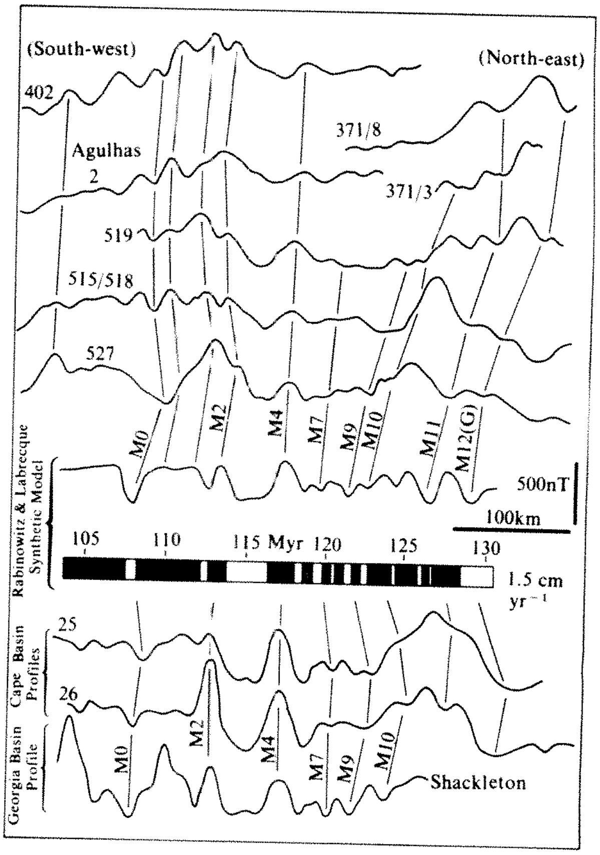

Fig. 2 Natal Valley magnetic profiles geographically aligned and correlated with respect to the magnetic block model of Rabinowitz and LaBrecque[1]. The model was generated by using a half spreading rate of 1.5 cm yr^{-1} for the Mesozoic reversal time scale of Larson and Hilde[4]. Profiles 402 (PR 2a), 371/8, 371/3, Agulhas 2, 519 (PR 3), 515/518 (PR 4) and 527 (PR 5) trend south-west–north-east within the Natal Valley sub-parallel to the Agulhas Fracture Zone. Notation in brackets refers to profile numbers used by du Plessis[10]. Profiles 25 and 26 (after ref. 1) from the Cape Basin and profile Shackleton (after ref. 11) from the Georgia Basin (immediately east of the Falkland Plateau) are included to show their general similarity to the Natal Valley traverses. Profile Shackleton is depicted as a mirror-image. Locations of profiles 25, 26 and Shackleton are shown in Fig. 1 insets.

Four previously published magnetic traverses[10] reassessed in conjunction with newly acquired data reveal a Mesozoic magnetic anomaly lineation pattern (Cape Sequence) within the southern Natal Valley (Fig. 2). Du Plessis[10] recognized magnetic lineations normal to the coast but did not correlate these with any published Mesozoic anomaly models[1,4]. The reinterpreted profiles (527, 515/518, 519, 371/3, 371/8, Agulhas 2 and 402) are geographically aligned and compared with the Mesozoic anomaly sequence of Rabinowitz and LaBrecque[1] in Fig. 2. Inter-profile correlation and correspondence to the synthetic model is good. The slight disparity of profile 527 with respect to the synthetic is suspected to be due to navigational inaccuracy. The Natal Valley and Cape Basin magnetic signatures parallel to the spreading direction show similarities (Fig. 2), confirming correct anomaly sequence identification.

We recognize anomalies M12 to M0 with correlation being particularly good for M4 to M0 (Fig. 2). Anomaly M4 is prominent in all profiles as a broad positive anomaly 250 nT in amplitude while the M2–M0 composite anomaly is conspicuous as a positive triple peak some 200–500 nT in amplitude. Lineations defining M11, M9 and M7 are less distinct but still considered valid (Fig. 2). However, identification of the Mesozoic Cape Sequence rests primarily on recognition of anomalies M4–M0.

The observed profiles provide a reasonable fit to the model[1] presented in Fig. 2 and thus 1.5 cm yr^{-1} is proposed as an average Mesozoic half-spreading rate for the Natal Valley. In detail, however, the M4–M0 rate appears slightly slower than the 1.5 cm yr^{-1} model (the anomalies are more compressed) while a slightly faster spreading rate (~1.7 cm yr^{-1}) may be appropriate to the M11–M4 sequence. These velocities are comparable with those calculated for crust immediately east of the Falkland Plateau in the Georgia Basin[11].

An areal plot of the magnetic traverses (Fig. 3) show the anomalies to be in sub-parallel alignment with a strike trend normal to the Agulhas Fracture Zone (defined here by the Cape Slope Anomaly[12]). Oceanic crust that was created directly east of the Falkland Plateau in the Georgia Basin should theoretically generate mirror images of Natal Valley magnetic profiles although these may now be distorted by differing ambient field declination, inclination and skewness. A profile from the Georgia Basin[11], plotted in reverse in Fig. 2, exhibits a degree of similarity to Natal Valley anomalies.

Recently, Martin *et al.*[3] proposed a revised fit of South America and South Central Africa (Fig. 1) primarily based on cross-continent alignment of three major pre-drift tectonic features: (1) the eastern and western boundaries of the submarine Jurassic Outeniqua Basin (Agulhas Bank) and the Falkland Plateau Basin; (2) the northern tectonic limit of the Triassic Cape Fold Belt (South Africa) and a closely contiguous major morphological feature on the Falkland Plateau; and (3) the late Precambrian transcurrent fault and mylonite belts of Pernambuco (Brazil) and Foumban (West Africa).

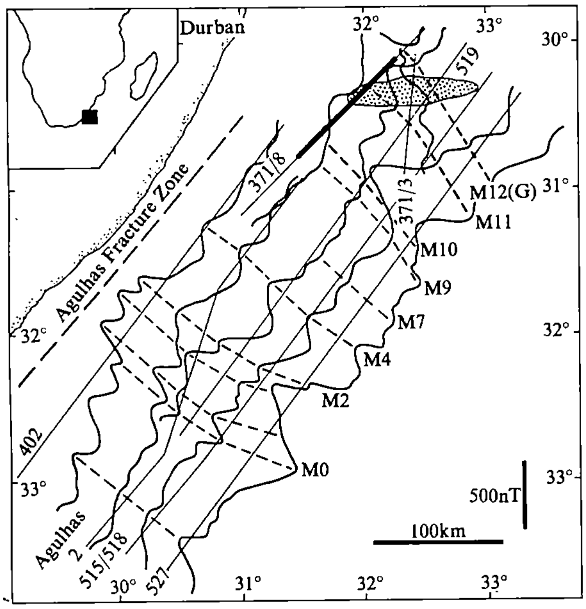

Fig. 3 Magnetic anomaly profiles plotted perpendicular to ship's tracks. Lines 402, 515/518, 519, 527, 371/3 and 371/8 were run between 1971 and 1977 on the *RV Thomas B. Davie*. Track Agulhas 2 was run on the *MV S A Agulhas* in August 1978. Inter-profile correlation identifying the Mesozoic anomaly sequence M12 (*G*) to M0 picked out by short dashed lines. Disparity of traverse 527 is suspected to be due to navigational inaccuracy. Note that the anomaly sequence trends normal to the Agulhas Fracture Zone (heavy dashed line adjacent to the coast). Enhanced portion of traverse 371/8 indicates location of the continuous seismic reflection profile depicted in Fig. 4. Dotted zone demarcates the seismically-defined extent of the South Tugela Ridge. Inset shows the study area in relation to southern Africa and Madagascar.

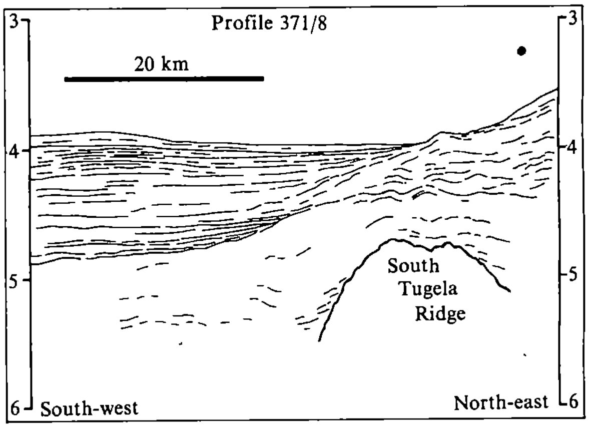

Fig. 4 Line tracing of continuous seismic reflection profile (371/8) showing the acoustic signature of the South Tugela Ridge. Profile location is shown in Fig. 3. Vertical scale is in seconds of two-way travel time.

This revised reconstruction[3] (total pole of rotation 46.75° N, 32.65° W; rotation angle 56.4°) is close to the refit of Rabinowitz and LaBrecque[1] but does not so tightly juxtapose conjugate margins of the Natal Valley and Falkland Plateau (see Fig. 1). This looser reconstruction[3] therefore removes suspected continental basement overlap in the Natal Valley and Precambrian basement overlap in the Gulf of Benin (West Africa)[3].

Seismic profiling surveys have delineated an approximately east–west oriented, deeply buried, basement ridge—the South Tugela Ridge (Fig. 4) underlying or immediately south of the steep Tugela Cone southern flank. The ridge location is depicted in Fig. 3. Significantly, in the revised reconstruction of Martin *et al.*[3], the South Tugela Ridge becomes juxtaposed to the continental–oceanic crust boundary (COB) of the Falkland Plateau as approximated by the 2,740 m isobath on seismic refraction results[5]. Independent geological–geophysical evidence therefore suggests that the South Tugela Ridge may be situated just north of the Natal Valley COB and is probably a result of initial rift volcanics intercalating with splintered continental blocks.

Within the Natal Valley, the oldest correlative magnetic anomaly is identified as M12 (Figs 2 and 3) and corresponds in character to anomaly *G* of Rabinowitz and LaBrecque[1,13]. Magnetic anomaly *G*, first mapped along the west coast of Africa[1,13], has been interpreted as a magnetic edge effect separating continental from oceanic basement. Reinforced by isostatic gravity modelling, Rabinowitz and LaBrecque use anomaly *G* to demarcate the COB. However, the west coast Africa magnetic lineation *G*, to which Rabinowitz and LaBrecque[1] assign an M12 age, has previously been dated as M13 by Larson and Ladd[14] using the same raw data; thus dating of this anomaly is not unambiguous.

The revised fit of Martin *et al.*[3] suggests that the south-west Africa COB may be sited ~40 km seaward of magnetic anomaly *G*, but still positioned within the landward gradient of the isostatic gravity anomaly. On the basis of reconstruction evidence[3], the Natal Valley COB is suspected to be located south of the South Tugela Ridge implying that anomaly *G* is placed on continental crust.

Utilizing the new palaeo-spreading pole of Martin *et al.*[3], the rotation of South America towards Africa achieves precise juxtaposition of Mesozoic anomalies (M0, M2, M4 and M10) in areas both south and north of the Agulhas/Falkland Fracture Zone. Thus, using only one set of rotation parameters, abutment of Cape and Argentine Basin anomalies[1] is simultaneous to abutment of the equivalent Natal Valley and Georgia Basin anomalies[11]. Complete kinematic description of the early spreading history will be more fully considered elsewhere. However, back-rotation to M10N (an anomaly intermediate to M10 and M11)[4] accomplishes optimum contiguity of the intercontinental structural lineaments previously described. We therefore postulate that opening of the South Atlantic commenced at ~125 Myr (M10N using the time scale of Larson and Hilde[4]).

Accepting this looser reconstruction as compared to that of Rabinowitz and LaBrecque[1] (see Fig. 1), it is necessary to explain the existence of recognizable magnetic lineaments (M11 and M12) landward of M10N (approximate COB) as demarcated in Figs 2 and 3. A possible explanation may be that before final separation, crustal rifting allowed extensive intrusion of volcanic lavas which were magnetized in the Earth's ambient field. This mechanism, with possible interference from basement topography and non-magnetized slivers of continental crust, may explain the poorer M11 and M12 correlation with the modelled profile (Fig. 2) and severe anomaly distension on several profiles. Larson and Ladd[14] likewise attribute poor correlation between anomalies older than M7 along the south-west Africa continental margin to disruption of the lineation pattern by the initial rifting phenomenon. Basement topography certainly induces modulation of the ambient field in this zone with high amplitude positive anomalies plotting over the South Tugela Ridge (Fig. 3, profiles 371/8, 371/3 and 519).

The collection of multichannel seismic data off the continental margin of south-west Africa[15,16] has cast additional doubt on the 'anomaly *G*' refit[1] of South America and Africa. In particular, Uchupi and Austin[15] locate their southwestern Africa COB at or closely seaward of the 3,000 m isobath. This placement is in general agreement with the reconstruction of Martin *et al.*[3] which likewise corroborates the new magnetic evidence presented here. Although the south-west Africa COB of Gerrard and Smith[16] is located even further seaward, constraints on data quality allow for some ambiguity in exact positioning (I. Gerrard, personal communication, 1981). These new multichannel data also imply that extensive intracontinental stretching took place along the passive margin of south-west Africa[15] during the early opening phase of the South Atlantic. However, the reconstruction of Martin *et al.*[3] in combination with the magnetic data outlined in this study suggests that post-breakup continental crust stretching may not have been active over the Falkland Plateau/Natal Valley zone.

We thank R. V. Dingle for a critical review, D. Murray and the CSIR for access to unpublished Agulhas 2 magnetic data, the Director of the Geological Survey for funding the project and permission to publish, and Mrs M. C. Hollander for typing the script.

Magnetic granulometry results for intrusive rock samples

G. S. Murthy & R. R. Pätzold

Geomagnetic Research Laboratory, Physics Department,
Memorial University of Newfoundland, St John's, Newfoundland,
Canada A1B 3X7

'Magnetic granulometry' techniques have been developed[1–4] to infer the domain state of magnetic minerals contained in rocks. Such techniques include study of the development of hysteresis of samples in fields of the order of 10 Oe (Rayleigh loops), study of hysteresis in high fields both at room temperature and at liquid nitrogen temperatures, and study of variation of magnetic susceptibility with temperature from −196 °C to 700 °C. These methods enable the magnetic properties to be quickly determined and so give an idea of the bulk magnetic behaviour of the rock sample. Although the usefulness of such methods for palaeomagnetic studies is limited because the remanent magnetic behaviour can be quite distinct from the bulk magnetic behaviour[5], in general, the granulometry method is a good supplement to regular experimental methods in palaeomagnetism. The study of several thousands of basalt samples by this method[6,7] has revealed insights into the magnetic behaviour of rocks. However, as part of the interpretive procedure of the method, the presence of low-field hysteresis loops has been considered a diagnostic feature of predominant superparamagnetic bulk behaviour of the rock sample. As we report here, we have observed, for the first time, low-field hysteresis loops associated with confirmed multi-domain magnetic grains, a possibility originally suggested on theoretical grounds by Néel[8].

Although the interpretation of results from granulometric experiments is controversial[7], there is agreement on the following basic points:

(1) A sample with multi-domain pure magnetite as the magnetic mineral will generally show $J_r/J_{\max} \sim 0.2$ with approximate doubling of coercivity as the temperature of the sample is changed from room temperature (25 °C) to liquid nitrogen temperature (−196 °C), a phenomenon consistent with earlier work[9,10]. As the magnetocrystalline anisotropy is more dominant than the shape anisotropy for multi-domain magnetic grains, magnetic susceptibility for this class of samples will be a function of the magnetocrystalline anisotropy constants K_1 and K_2. Because K_1 and K_2 change sign at approximately −150 °C (refs 11, 12), an isotropic point with resultant susceptibility peak occurs close to that temperature. Low-field hysteresis loops for this class of samples have not previously been observed, and Fig. 1*a*, *d*, *g* shows their characteristics.

(2) A sample with single-domain magnetite as the magnetic mineral will have $J_r/J_{\max} = 0.5$ at room temperature, increasing to 0.8 at −196 °C, with a corresponding increase in coercivity. For this class of samples, due to the dominance of shape anisotropy over magnetocrystalline and/or stress anisotropy, the susceptibility peak at the isotropic point would be suppressed and a monotonic susceptibility decrease is usually observed as the temperature is lowered from 25 °C to −196 °C. This class of samples does not exhibit Rayleigh loops. Typical results are shown in Fig. 1*b*, *e*, *h*.

(3) In the class III samples, which were interpreted as being due to the predominantly superparamagnetic bulk behaviour of the sample, Rayleigh loops would be observed[13,14], due to the interaction of clusters of superparamagnetic grains. The high-field hysteresis would show $J_r/J_{\max} \sim 0.2$ at 25 °C, increasing to >0.80 at −196 °C, with a substantial increase in coercivity due to grains which are superparamagnetic at room temperature becoming effectively single-domain at −196 °C because of the lowering of the thermal energy. The susceptibility–temperature

0028–0836/82/080688—03$01.00

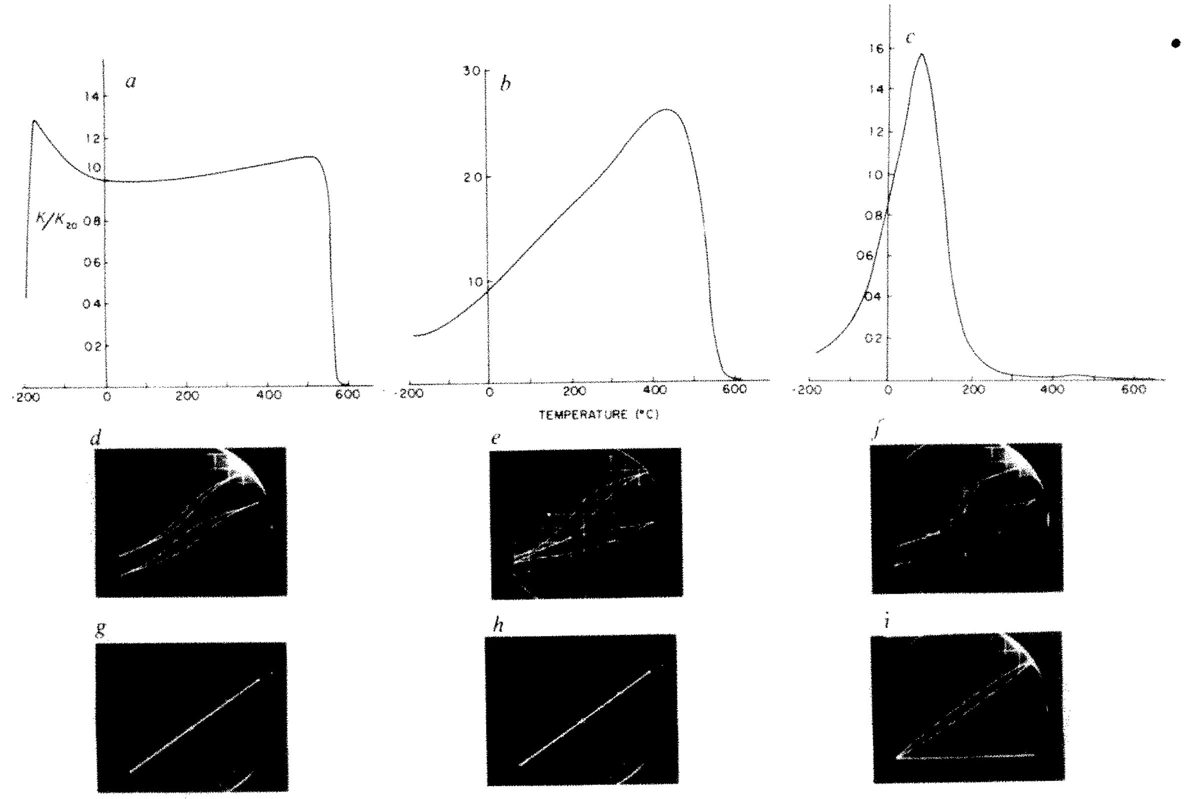

Fig. 1 Basis for interpretation of magnetic granulometry. *a–c*, Normalized susceptibility versus temperature; *d–f*, magnetic hysteresis in a field of 1,200 Oe at room temperature (upper trace) and at −196 °C (bottom trace); *g–i*, Rayleigh loops in a field of 10 Oe. *a*, *d*, *g* are typical responses for class I behaviour (multi-domain) as obtained on G215C, a dolerite dyke sample from Newfoundland; *b*, *e*, *h* are typical responses for class II behaviour (single domain) as obtained on a basalt sample from a DSDP drill hole; *c*, *f*, *i* are typical responses for class III behaviour (superparamagnetic) as obtained on a basalt sample from a DSDP drill hole.

curve would show a decrease in normalized susceptibility to ~0.2 at −196 °C and a location of the peak which differs in different samples, but which is nearly always at temperatures <300 °C, followed by a long tail. Figure 1*c*, *f*, *i* shows typical results exhibited by a member of this class of samples. Class III and class II behaviours were previously designated type 1 and type 2[15,16].

The most controversial aspect of this interpretation is the inference of superparamagnetic grains from the presence of Rayleigh loops and the typical susceptibility–temperature curves of the class III type. The observed grain sizes in most rocks exhibiting this behaviour are of the order of hundreds of micrometres, and for the grains to behave like superparamagnetics, they must be effectively subdivided into SP sizes. The question arises of why the observed Rayleigh loops are not due to multi-domain grains. Néel[8] alluded to the possibility of multi-domain grains exhibiting hysteresis in low fields. The BH_c/A parameter (where B and A are the quadratic and linear coefficients of Rayleigh relation and H_c is the bulk coercive force) for such loops will be of the order of 0.05, while the value for this quantity for the observed loops[13,15] is of the order of 10. The reason cited by Néel for the smaller BH_c/A for multi-domains is that the demagnetizing factor is to be taken into account for multi-domains. In all the thousands of measurements conducted to date, all confined to basalt samples, a Rayleigh loop was never found associated with K–T curves and hysteresis loops of the class I type. Due to the observed association of the susceptibility–temperature variation for the multi-domain samples, well established in theory and experiment, with the corresponding 'absence' of Rayleigh loops for such samples, the established granulometric interpretation was that Rayleigh loops exhibited by multi-domain samples cannot be seen. In particular, it was noted[15] that on the present Rayleigh loop tracer, a multi-domain Rayleigh loop, with its low BH_c/A value, would not be wider than the thickness of the oscilloscope trace itself.

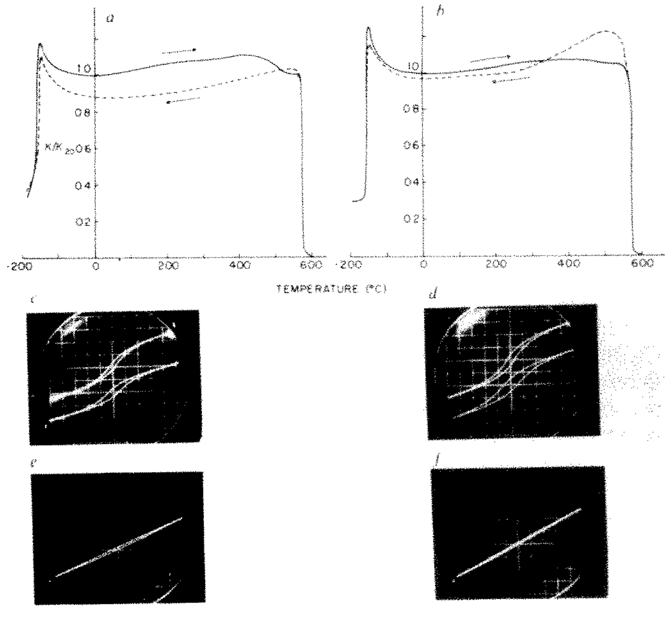

Fig. 2 Magnetic granulometry results: *a*, *c*, *e*, for GR353C, a dolerite dyke sample from the Grenville Province of the Canadian Shield; *b*, *d*, *f*, for N-69.1, an anorthosite sample from Nain, Labrador; *a*, *b*, normalized susceptibility versus temperature; *c*, *d*, magnetic hysteresis in a field of 1,200 Oe at 25 °C (upper trace) and at −196 °C (bottom trace); *e*, *f*, Rayleigh loops in a field of 10 Oe.

We extended the granulometric studies to older intrusive rocks (dolerite dykes, anorthosites and gabbros). Samples studied include the Grenville dykes, Indian Head and Nain anorthosites, and gabbros from Newfoundland. Earlier palaeomagnetic studies of these rock units revealed that their remanent magnetism is extremely stable (Koengsberger ratios ~10) and that their remanence, particularly for the anorthosites, resided in elongated magnetite grains exsolved within the silicates. The present systematic studies include: (1) magnetic susceptibility variation from −196 °C to 700 °C; (2) hysteresis loops at −196 °C and at room temperature in a field of 1,200 Oe (note that a 1,200-Oe field may not always result in saturation of the sample); (3) Rayleigh loops in a field of 10 Oe.

Most samples are class I type; class II and III types are virtually absent. This confirms the earlier conclusions[6] that most 'old' rocks are predominantly multi-domain in nature and that superparamagnetic behaviour is virtually absent in the 'old' rocks. However, many samples exhibited a new type of behaviour—a Rayleigh loop at low fields, associated with class I type hysteresis and K–T curves. Typical examples of results for this behaviour are shown in Fig. 2 for two samples, a dolerite dyke and an anorthosite. These samples do not fall into the three classes discussed earlier. Whereas the presence of Rayleigh loops suggests SP behaviour, the K–T curves and the high-field hysteresis strongly favour the multi-domain state. An explanation in terms of mixtures[3] does not hold here, as experiments lead to different inferences according to the previous interpretation (Fig. 1). Further, an SP component in a mixture should have modified the K–T curve from what is now a 'pure' multi-domain curve. Therefore, there is no doubt that the bulk magnetic properties of these samples, including their Rayleigh loops (Fig. 2*c*, *f*) are caused by magnetite in the multi-domain state. The value of the BH_c/A parameter for these loops is similar to some of the lower values in previously observed loops inferred as being due to effectively superparamagnetic grains.

It is possible that the observed Rayleigh loops reported here are due to a highly conducting nature of the samples (C. Radhakrishnamurty, personal communication) and the resulting eddy currents. Although the conductivity of these samples is of the same order as that of other intrusive rocks of the type studied by us, we tested for this possibility by crushing some of the samples to fine (<50 μm) sizes and remeasuring the Rayleigh loops. The Rayleigh loops were still present, although in slightly diminished thicknesses. We conclude that the observed Rayleigh loops for our samples are real and are not due to eddy current effects. This leads to the following possibilities. (1) With the K–T curve being the main diagnostic feature of multi-domain nature of a magnetic grain (class I type), two types of multi-domain behaviour exist: those samples that do not exhibit a Rayleigh loop and those that do show a Rayleigh loop. (2) Rayleigh loops associated with class III type K–T curves may be interpreted as due to magnetic grains being in a superparamagnetic state. (3) Exhibition of Rayleigh loops is a necessary condition for SP behaviour but is not a sufficient diagnostic feature. Further work is required to clarify these possibilities.

We thank Dr C. Radhakrishnamurty for discussions and advice on various aspects of this observation, and Professor E. R. Deutsch for a critical review of the manuscript. This work was supported by a Natural Sciences and Engineering Research Council of Canada operating grant to G.S.M.

Explicit dialogue between left and right half-systems of split brains

D. M. MacKay & Valerie MacKay

Department of Communication and Neuroscience,
University of Keele, Keele, Staffordshire ST5 5BG, UK

Much debate has surrounded the interpretation of the well known 'split brain' syndrome, produced by section of the corpus callosum in man [for useful surveys of early studies of the effects of callosal damage (for example by Liepmann (1900), Goldstein (1908) and Bonhoeffer (1914)) see refs 1–3]. On the basis of the observation that left and right half-systems can find themselves in conflict when disparate instructions are flashed to left and right visual hemifields, Sperry[4] has described such patients as having "two free wills inside the same cranial vault". MacKay[7–9], among others, has argued for a more parsimonious interpretation of the available evidence, suggesting that it demonstrates duality only at the 'executive' level where continuous goal-pursuit is administered, rather than at the 'normative' supervisory level where the agent's priorities and criteria of evaluation are themselves subject to evaluation and revision. We report here some experiments in which a split-brain patient showed considerable capacity for explicit interhemispheric exchange of information and instructions, yet gave no sign of the duality of supervisory initiative that might have been expected on the hypothesis of 'two free wills'.

Gazzaniga and co-workers[6,10] have shown both in monkey and man that each hemisphere can apply disparate criteria of evaluation to the same stimulus, as well as expressing disparate preferences in the same situation. This indicates convincingly that both evaluative and organizing systems are split at the executive level, but it falls short of proof that the brain in such patients embodies two independent systems for evaluating priorities themselves—the characteristic human activity with which the term 'will' is associated.

One relevant question is whether, and if so to what extent, one 'half-system' in these cases can be induced to demonstrate any recognition of the other half-system as 'another person', Through the generous cooperation of R. W. Sperry and M. S. Gazzaniga, we have recently contrived a number of laboratory situations designed to give systematic opportunities for such 'interpersonal' types of interaction. Some of these have been described elsewhere[9]. In the case described here our strategy was to train each 'half' in turn to engage in interpersonal exchanges with an experimenter in a simple competitive guessing game, and then to encourage each to use its acquired symbolic skills to engage the other 'half' in the same manner. The question was whether we would see any signs of simultaneous conscious evaluation of priorities from disparate standpoints, such as would be shown by two conscious human agents in a bargaining situation.

The patient (J.W.) was a right-handed 27 yr-old man who had had his corpus callosum, but not his anterior commissure, sectioned in 1977 to help prevent the spread of epileptic seizures from one hemisphere to the other[11]. Apart from side effects of anticonvulsant medication he was in good health, and cooperated with enthusiasm in the experiment. Preliminary tests confirmed observations by Sidtis *et al.*[12] that he was unable to report vocally any visual stimuli flashed to the left of his fixation point, although his left hand could correctly point to or retrieve objects represented by these stimuli. A single numeral randomly selected from the range 0 to 9 was flashed for 150 ms at an eccentricity of 4° to the left of the fixation point, simultaneously with a distractor (one or more letters of the alphabet) flashed at a similar eccentricity to the right. J.W. reported vocally that he saw only the distractor. Both vocal and right-manual responses were normal for stimuli flashed to the right half-field.

0028–0836/82/080690—02$01.00

Each half-system in turn was then trained to participate (on opposite sides) in a guessing game of the '20 questions' type in dialogue with one experimenter (E).

(1) E first assumed the role of 'guesser', attempting to name a 'mystery number' written by the second experimenter on a piece of paper in free view of J.W. E invited J.W. to use his left hand to point to appropriate answers on a card also in free view, bearing the words 'go up', 'go down', 'OK'. The left hand proved immediately capable of providing reliable feedback in this mode.

(2) E then invited J.W. to "guess a number between 0 and 9 which I have been shown". In response to each guess by J.W., E pointed mutely to one of the three messages on the card. J.W. quickly learned to adapt his vocal guesses so as to home in on the correct answer under this mute feedback from E.

(3) Finally, single digits between 0 and 9 were flashed as before to J.W.'s left half-field, with distractors to the right; and E proposed that J.W. should fulfil both roles, using his mouth to make guesses and his left hand to offer feedback by way of the card. J.W. found no apparent difficulty in fulfilling this dual role, although it was notable that all his guesses were addressed to E, who invariably had to ask the left hand to answer. He proved well able to 'talk himself down' on to the correct target each time, frequently showing satisfaction by a smile when the target was finally named. A useful check that he was not just play-acting (which seemed in any case improbable) was provided by an episode when his mouth guessed '1' and his left hand pointed to 'go down'. J.W. complained vocally that there were "no more numbers down there", and had to be reminded of the possibility of '0' (which was the correct answer).

These results make clear that symbolic information-exchange by question and answer can be sustained between left and right half-systems of a split-brain patient. Various forms of cross-cueing have, of course, been known and studied in such patients for many years[13]. Sidtis *et al.*[12] have also shown that a '20 questions' guessing procedure on the part of an experimenter could help a patient with a partially sectioned corpus callosum to 'home in on' the name of a stimulus flashed to the left half-field; but it was by no means obvious that J.W.'s two half-systems could use a public symbolic system of this kind to engage in systematic dialogue with one another.

However, we are still left with the vexed question of whether the two half-systems here embodied 'two free wills' in the sense in which, say, two normal human players on opposite sides of a guessing game have independence of will. An ideal demonstration of such 'duality of will' would be the capacity to bargain: that is, to struggle to induce changes in one another's evaluative criteria or priorities as distinct from merely struggling physically in pursuit of conflicting goals[8,9].

Accordingly, E next proposed to J.W. that "the left hand (LH) should be paid by the right hand (RH) for each item of information". RH was provided with an open box containing a limited supply of tokens, and instructed to pay one token into a similar box on the left for each correct answer by LH. RH was rewarded (with additional tokens) in inverse proportion to the number of guesses required to identify each flashed numeral. Any occasional mistakes made by LH were penalized by repaying three tokens per mistake to RH.

As elaboration of the game in this way proved congenial to J.W., we next introduced the possibility of evaluative conflict by proposing to "ask the left hand whether it would like to be paid more for each answer". LH was asked to reply by pointing to a card representing one, two and three tokens; and it immediately indicated 'three tokens'. As this soon had the (foreseeable) effect of rendering RH bankrupt and halting the game, E then said "Let's ask the left hand whether it would settle for less". LH immediately pointed to 'two tokens'; but at the same time, and apparently as an integral part of the action, J.W.'s mouth said "Sure, make it two tokens". This was typical of the impression conveyed throughout this second phase of the experiment—that although J.W.'s LH and RH were substantially separate at the cognitive level, their priorities gave no evidence of being under the supervision of two independent normative systems[7–9].

It is, of course, impossible to draw firm conclusions from such negative evidence. One can always explain absence of conflict by postulating suppressive (internal) influences from one half-system on normative processes in the other that would otherwise be independent; alternatively, it could be argued that the two half-systems perceived the rewards as jointly shared, and thus had no incentive to quarrel (M. S. Gazzaniga, personal communication). Our evidence is consistent, however, with the null hypothesis that at the higher levels of supervisory evaluation J.W. has not two half-systems but one undivided system, presumably associated with deep neural structures not surgically separated. This null hypothesis is strengthened by the well known fact[5,6] that emotive stimuli to the mute hemisphere can elicit signs of corresponding emotion in the speaking subject. At least, the onus of proof seems now to rest on anyone who would claim that patients like J.W. have, nevertheless, 'two free wills'. Perhaps his own spontaneous comment, offered more than once, is illuminating: "Are you guys trying to make two people out of me?"

These experiments were possible only through the generous cooperation of Dr M. S. Gazzaniga and his colleagues, particularly Drs Jeffrey Holtzman, John Sidtis and Bruce Volpe, in the Division of Cognitive Neuroscience at Cornell University Medical College in New York City. We also thank J.W. for his willing participation. Financial support was received from a Sloan Foundation Grant to Dr Gazzaniga, from the University of Keele to D.M.M. and from the Wellcome Trust to V.M.

Somatotopic maps are disorganized in adult rodents treated neonatally with capsaicin

The somatosensory system is characterized at each stage of the projection pathways by the presence of maps formed by an orderly arrangement of cells and of the incoming fibres. Each cell responds to a definite area of skin, its receptive field (RF). If cell locations and their RFs are plotted side by side, they make up a continuous map of the body surface. Given the stability and repeatability of these maps, it was of interest to find that lesions which destroyed the input to one part of the map of the spinal cord in adults were followed by a readjustment of the RFs of cells which had lost their normal input[1]. It was more surprising to discover in adult cats and rats that peripheral nerve lesions which do not produce an anatomical destruction of spinal cord afferents were followed by the appearance of novel RFs in cells

0028–0836/82/080691—03$01.00

deprived of their normal physiological input[2,3]. Capsaicin given to neonatal mice or rats destroys unmyelinated afferents. We report here that this is followed by an expansion of the normal receptive fields supplied by myelinated afferents[2,3]. Our results suggest that unmyelinated fibres may be involved in controlling the connectivity of myelinated afferents with first central cells.

Experiments in rats show that the foot and toe representation is present in the medial two-thirds of the dorsal horn of segments L4 and L5 of the spinal cord. If this region is searched to a depth of 1 mm with fluid-filled microelectrodes in intact adult rats anaesthetized with Nembutal, an average of five cells responding to the foot or toes are isolated in each track. As the RFs remain stable over many hours of recording and since the maps are accurately repeated from animal to animal, it is reasonable to expect that abolition of a particular input would silence the cells which are normally dominated by that input. We therefore searched the same region with a total of 51 tracks in 13 animals in which the sciatic and saphenous nerves that supply the foot had been cut on the day of the experiment, and found only 0.1 responding cells per track; these few RFs were on the leg. The same virtual absence of responding cells was observed in six animals 2 and 3 days[3] after the nerves had been cut. However, in 13 animals with a total of 69 tracks surviving 4–8 days after nerve section, the value rose to 3.2 cells per track. All these RFs were on the upper leg and pelvis and were supplied by intact nerves[3]. Similar results have been seen in the cat following peripheral nerve section[2]. These new RFs in the foot region could not have been supplied by sprouts growing from the nerve sectioned 4–8 days earlier because resectioning of the nerve on the day of the experiment produced no change in the recordings.

Lesions of nerves in the hind legs, unlike root lesions, produce no frank degeneration of central afferent terminals in the spinal cord for at least 2 weeks after the lesion[2,3], but they do interrupt impulse and chemical transport from the periphery to the spinal cord. We suspected that the component of the peripheral nerve responsible for signalling to the spinal cord that the peripheral nerve was cut might be the unmyelinated C fibres, as anatomical and chemical changes have been reported in their spinal cord terminals and not in the terminals of myelinated afferents following peripheral nerve section[4–6].

Capsaicin, the hot compound in paprika, produces rapid, substantial and permanent destruction of C fibre sensory afferents in dorsal roots and in the trigeminal nerve if injected into neonates[7–10]. This effect seems to be remarkably specific. Ultrastructural studies of cord and trigeminal nuclei show only degeneration of the terminals of fine afferents on laminae I and II[11,12]. Immunochemistry reveals depletion of substance P only in dorsal horn, trigeminal nuclei, nerves and roots, with no depletion in ventral horn or elsewhere in the brain[12–14]. The drug has no effect on enzymes and peptides intrinsic to the dorsal horn: neurotensin, glutamic acid decarboxylase and catecholamine amine transferase[12,15]. Unlike capsaicin given systemically to adults, there is no evidence that neonatal capsaicin produces hypothalamic damage[16]. In our hands the peripheral lesion seems to be limited to the unmyelinated afferents[9], but others have reported a small and variable loss of some myelinated fibres with high doses[8,10].

Litters of Sabra and Wistar rats under ether anaesthesia were injected with capsaicin (50 mg per kg intraperitoneally) dissolved in 10% Tween 80, 10% ethanol in saline on the second and fourth day of life. Littermates were injected with the vehicle. The animals were returned to their mothers and allowed to grow to adults weighing over 200 g. They were apparently healthy, with normal sleeping, eating and grooming behaviour and no deficit in motor activity.

The effectiveness of the drug was tested in three ways. First, the peripheral C compound action potential was measured by stimulating the dorsal root (5 mA, 500 μs) and recording from the sural nerve at the beginning of each experiment. A C wave was never recorded in capsaicin-treated animals from dorsal root stimulation ($n = 4$) whereas in vehicle-treated animals and untreated controls a clear C compound action potential was evoked. Second, the spinal cords were removed from four animals and stained for immunoreactive substance P. Substance P is normally highly concentrated in the region of small fibre terminals in the dorsal horn[17] and in all the tested cords it was substantially depleted. Finally, cords from three rats were stained for fluoride-resistant acid phosphatase[4]. Again, there was substantial depletion of the enzyme from the dorsal horn terminals. Four vehicle control littermates were also tested by these three methods and the measurements were normal. It therefore appeared that the rats treated neonatally with capsaicin had lost a substantial number of their peripheral C fibres.

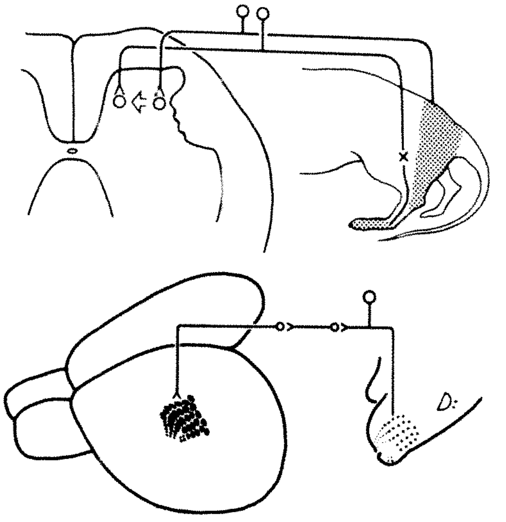

Fig. 1 Above: In the normal rat, the nerves from the foot and toes project to the medial part of the lumbar dorsal horn. The proximal parts of the leg project to the lateral cells in the dorsal horn. If the nerves to the foot are cut in normal animals, most of the medial cells fail to respond to peripheral stimulation for a period of 0–3 days after the cut. During the period 4–8 days after nerve section, many medial cells begin to respond to stimulation of proximal leg. In animals treated neonatally with capsaicin, medial cells respond to the upper leg immediately after peripheral nerves to the foot have been cut. Below: In the normal mouse, each individual large whisker projects by way of the trigeminal nerve, the trigeminal sensory nuclei and the thalamus to the cortex. In the parietal cortex there are barrels of cells in which each cell responds to the movement of one whisker only. Almost all responding cells in an individual barrel respond to the same single whisker. In mice treated with capsaicin soon after birth, the barrels and whiskers are present in their normal arrangement but no cell was encountered which responded to only one whisker. All recorded cells responded to 2–7 whiskers (average 3.8).

The spinal cord maps of 10 neonatally capsaicin-treated rats, 6 vehicle-treated and 4 untreated control animals were then examined. Low-thoracic spinalized preparations were used to increase the excitability of the cord and therefore reveal any aberrant cells in control animals. The rats were either anaesthetized with Nembutal or decerebrated under short-acting Althesin anaesthesia. The saphenous and sciatic nerves were cut acutely at knee level on the day of the experiment and the medial dorsal horn of segments L4 and L5 searched with electrode tracks for cells that responded to skin stimulation on the upper leg above the knee.

In normal and vehicle controls under Nembutal anaesthesia, 0.9 cells were found per track ($n = 43$). Decerebrate controls showed 1.8 responding cells per track ($n = 31$). This region was therefore clearly largely silenced by acute denervation of the lower limb, the actual number of responding cells being somewhat dependent on the excitability of the cord in different preparations. In capsaicin-treated animals with acute deafferentation of the foot, 2.6 cells per track ($n = 64$) were found in six Nembutal-low spinal animals. In the decerebrate preparations, the four treated animals had 6.7 cells per track ($n = 15$). The number of aberrant RFs in the foot area was significantly greater in the capsaicin-treated animals than in controls ($P<0.001$, t-test). The receptive fields were on the upper leg and in some cases (1.2 cells per track) extended to the tail and over to the contralateral limb. The responses were induced by firm pressure or pinch and often also by light touch. Thus, the capsaicin-treated animals have the same type of distorted somatotopic cord map after acute peripheral nerve section as occurs in normal rats after chronic nerve section.

The somatotopic map of spinal cord is not as detailed as that in the somatosensory cortex. A particularly precise and extensively investigated projection is that of the whisker follicles mapped on the parietal cortex of the mouse, in which an anatomical correlation is established between individual whiskers and discrete cytoarchitectonic units in the parietal neocortex, the barrels[18]. Furthermore, Van der Loos and Woolsey[19] showed that limited neonatal lesions of particular whiskers resulted in failure of development of the corresponding barrels. It was later shown that the occasional appearance of an extra whisker is associated with an extra barrel in the topologically equivalent cortical locus[20]. Following previous studies on cortical physiology of whisker responses[21,22], Nussbaumer (manuscript in preparation) has examined the details of the physiological aspect of this tight anatomical mapping in mice and has found an extraordinary specificity of both anatomical and physiological correlation between the periphery and its cortical representation. In penthrane/nitrous oxide-anaesthetized mice, 117/121 tracks through layer IV of these cortical barrels revealed cells responding to only one whisker. In the remaining four tracks, the cells responded to two neighbouring whiskers. In view of this finding, it was obvious that we should test the effect of neonatal capsaicin. Two litters of mice (CBA/CA and ICR) were treated on the second and fifth day of life with 50 mg capsaicin per kg in the same manner as the rats. Littermates were treated with the vehicle alone. The animals were returned to their mothers, allowed to grow to adulthood and examined after more than 4 months.

In two vehicle-treated controls the cortex showed the same results as in normal mice in that five marked penetrations into layer IV of the barrelfield revealed cells responding to only one whisker. In the capsaicin-treated mice of both strains, the cortical anatomy as observed in Nissl preparations showed normal barrelfields. The size and distribution of whiskers were also normal. However, on penetrating the cortex, the recordings were strikingly abnormal. In two CBA and three ICR mice examined with a total of 18 penetrations, each penetration yielded one or more responding cells. No recording sites showed cells responding to only one whisker. The number of whiskers that could excite a cell varied from 2 to 7 (average 3.8). Invariably the whisker producing the most intense excitation was that which would normally have monopolized the barrel within which the recording was being made.

These experiments show that the RFs of some cells in rat spinal cord and in mouse cortex are greatly expanded in adults treated neonatally with capsaicin (Fig. 1). In spinal cord, it has been shown by electrical stimulation of the skin that many of the cells with expanded RFs are excited monosynaptically by myelinated afferents[2,3]. The abnormal RFs of these cord cells may therefore be produced by abnormal coupling of myelinated afferents to central cells. For the mouse cortex cells with expanded RFs, a similar explanation would apply if trigeminal myelinated afferents establish abnormal contacts with cells in the trigeminal sensory nuclei.

These results suggest a testable hypothesis that the normal receptive fields of cord and medulla cells excited by myelinated sensory afferents require the presence of unmyelinated afferents. We propose that the effect of neonatal capsaicin is limited to its destruction of afferent fibres in the periphery. This is supported by the absence of signs of direct central destruction[11,12,16], and by results to be reported elsewhere[23] that local application of capsaicin to a single nerve in the adult also results in abnormal expanded receptive fields limited to cells supplied by the treated nerve. Although it is possible that the toxin has produced some subtle undetected change in the myelinated afferents, in the case of single nerve lesions it is evident that the novel receptive fields are supplied by myelinated afferents which were not touched by the lesion. We therefore propose that unmyelinated afferents have a role in the establishment of ordered connections between myelinated afferents and the first central cells.

Neural cell adhesion molecule is on embryonic muscle cells and mediates adhesion to nerve cells *in vitro*

Martin Grumet, Urs Rutishauser
& Gerald M. Edelman

Department of Molecular and Developmental Biology,
The Rockefeller University, 1230 York Avenue, New York,
New York 10021, USA

The interaction of nerves with muscles, particularly at neuromuscular junctions, is one of the most extensively studied areas of neurophysiology. From the point of view of developmental biology, however, little is known about the cellular and molecular events that lead to formation of these junctions[1,2]. In previous investigations of cell–cell adhesion in the chick embryo, we identified a molecule on the surface of essentially all nerve cells, called neural cell adhesion molecule (N-CAM)[3,4], that appears to be a ligand in the formation of cell–cell bonds[5]. N-CAM is involved in a variety of developmental processes including neurite fasciculation and the formation of plexiform and cell layers in retinal tissue[6–8]. We report here that N-CAM antigenic determinants are also present on chick embryo skeletal muscle cells. This observation raised the possibility that N-CAM is involved in adhesion between nerve and muscle cells. In model systems set up to explore this possibility, we observed that myoblasts will adhere *in vitro* to nerve cells from retina, and that this adhesion can be inhibited by F(ab′) fragments of antibodies against N-CAM. In addition, membrane vesicles obtained from chick embryo brain or artificial vesicles[5] reconstituted from lipid and affinity-purified N-CAM[9] bound to the surface of myoblasts and myotubes; this binding was also blocked by anti-N-CAM F(ab′). These results suggest that the N-CAM adhesion system can facilitate nerve–muscle as well as nerve–nerve interactions *in vitro*.

Immunocytological studies carried out to determine the distribution of N-CAM in chick embryos revealed that the molecule is associated with nerve tissues; however, light staining was also observed in muscle[6]. As shown in Fig. 1, rabbit anti-N-CAM antibodies that had been affinity-purified on N-CAM–Sepharose[5], bound to the surface membrane of cultured skeletal myoblasts and myotubes but not to fibroblasts in the same

0028-0836/82/080693—03$01.00

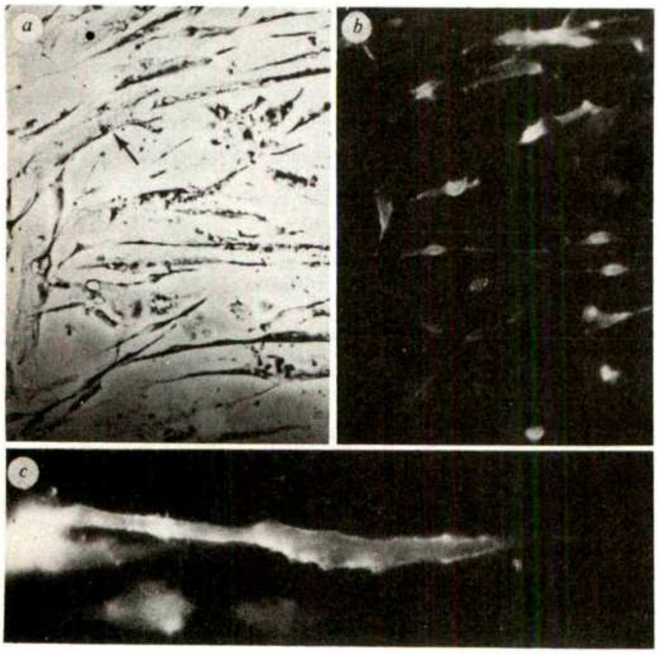

Fig. 1 Immunofluorescence staining of skeletal muscle cells with antibodies to N-CAM. *a*, Phase-contrast micrography of myoblasts and early myotubes (×264), and *b*, fluorescence micrograph of the same field. *c*, Fluorescence micrograph of a myotube. ×880. A fibroblastic cell which is not stained is indicated with an arrow. Muscle cells were obtained from 11–12-day White Leghorn chick embryo legs by trypsinization (0.1%, 30 min, 37 °C) and trituration, and partially separated from fibroblasts by differential adhesion to culture dishes; the nonadherent cells were cultured on collagen-coated substrates for 2 days in Eagle's modified essential medium containing 10% horse serum and 5% chick embryo extract. For staining, the cultures were treated sequentially with 3.7% formaldehyde, 0.1 M glycine, 4% goat serum, affinity-purified rabbit anti-N-CAM IgG and fluorescein-labelled goat anti-rabbit IgG (Miles-Yeda). All reagents were prepared in phosphate-buffered saline; each antibody treatment was followed by four washes with buffer.

cultures. The staining of the muscle cells, which had been prefixed with formaldehyde, was mostly diffuse and lower in intensity than that seen previously on neurones[6]. Immunoglobulin from unimmunized rabbits did not give detectable staining.

The presence of N-CAM antigenic determinants on muscle cells suggested that at some stage of their development they might adhere to nerve cells through this molecule. This possibility was examined by studies of the adhesion of skeletal muscle myoblasts in suspension to monolayers[10] of retinal nerve cells, of the co-aggregation of these cells in rotation–suspension cultures and of the binding of membrane vesicles containing N-CAM to myoblasts in suspension and to myotube monolayers. Although these assays represent highly simplified model systems for the analysis of cell–cell interactions in developing tissues, they have been useful in revealing and quantifying specific adhesion events, in particular for studying their molecular basis[3,10,11]. The use of retina and brain for these studies reflects the requirement for substantial numbers of cells in the binding assays. Although retinal cells can establish a weak and transient synaptic connectivity with muscle *in vitro*[12], this system is of limited use in evaluating nerve–muscle interactions *in vivo*. Nevertheless, spinal cord cells are known to express N-CAM[6], and the results obtained here will provide the necessary background to interpret more complex studies, such as the effects of anti-N-CAM antibody on cultures of muscle cells with spinal cord explants.

Adhesion between nerve cells has been measured previously using a cell suspension–cell monolayer binding assay[10]. In the present studies, myoblasts in suspension also bound to a retinal nerve cell monolayer, the level of binding during a 20-min incubation being about one-half that observed between nerve cells (Table 1). This binding was inhibited by anti-N-CAM F(ab′) and did not require the presence of Ca^{2+}; by these criteria it is distinguishable from the calcium-dependent mechanism of nerve cell adhesion[13]. Fibroblasts, which lack N-CAM[6], did not bind in significant numbers to the retinal nerve cell monolayer.

Further evidence for nerve–muscle adhesion was obtained by incubating retinal and muscle cells together in suspension at 70 r.p.m. and 37 °C for 20 min; in these conditions large aggregates were formed that contained both cell types (Fig. 2). Similarly, fluorescein-labelled membrane vesicles obtained from brain tissue bound to myoblasts and myotubes (Table 2, Fig. 3), although less strongly than to retinal neurones (Table 2). In each case, the interaction was inhibited by anti-N-CAM F(ab′); fibroblasts were included as a control and did not bind the vesicles. Table 2 and Fig. 3 show the binding to muscle cells of vesicles reconstituted from brain lipids and purified N-CAM. This adhesion was almost completely inhibited by anti-N-CAM antibody; vesicles containing lipids alone bound only in small numbers to a few cells. Binding was also observed between the N-CAM vesicles and cells obtained from heart muscle of 9-day embryos by trypsinization as described for the retinal cells. This suggests that N-CAM-mediated interactions may take place in a variety of muscle tissues of different origins.

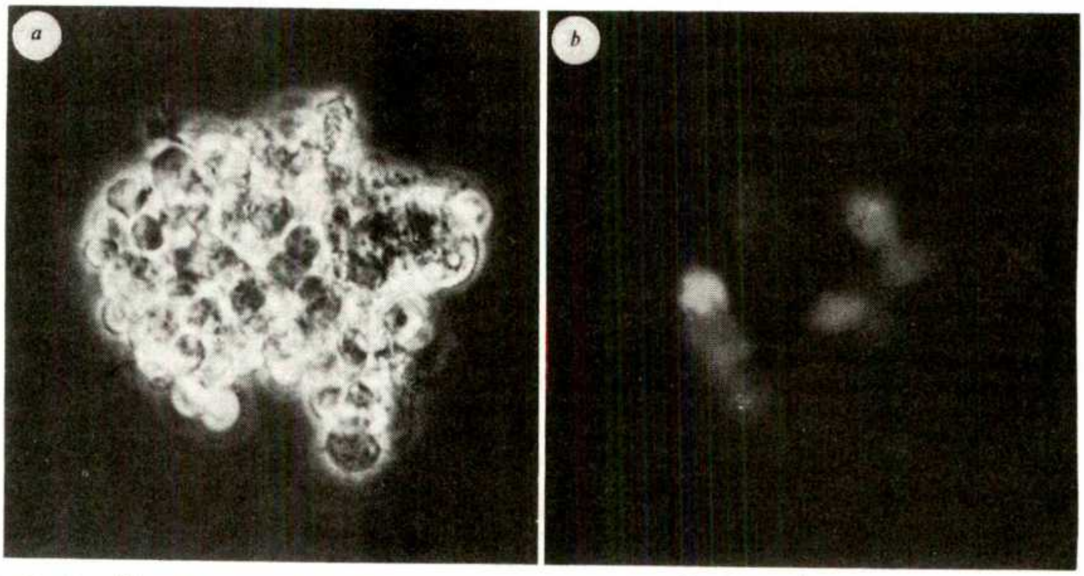

Fig. 2 Co-aggregation of retinal nerve cells with fluorescein-labelled myoblasts. *a*, Phase-contrast micrograph, and *b*, fluorescence micrograph of the same field, ×840. Cells (2.5×10^6 of each type) were incubated in 1 ml Eagle's minimal essential medium with spinner salts (SME medium) for 20 min at 37 °C with rotary shaking at 70 r.p.m. Myoblasts were prepared as described in Fig. 1 legend, cultured in suspension for 4 h and further fractionated by density gradient centrifugation in Ficoll to yield a cell population consisting of about two-thirds myoblasts, the remaining cells probably being fibroblasts[14]. Myoblasts were internally labelled with diacetyl fluorescein[10]. Nerve cells were obtained from retina of 10-day chick embryos by mild trypsinization (0.002%, 15 min, 37 °C)[13].

We have shown previously[5] that the adhesive specificity and the properties of the reconstituted N-CAM vesicles closely resemble those of intact nerve cells and have obtained evidence suggesting that cell–cell binding may involve interactions between N-CAM molecules on different cells. The fact that both muscle and nerve cells have N-CAM on their surfaces is consistent with this hypothesis. It also raises the possibility that muscle cells could bind to each other in part by the N-CAM mechanism. In preliminary studies, however, anti-N-CAM F(ab′) reduced the binding of myoblasts to myoblasts or myotubes by only ~20%, which may indicate that other adhesion mechanisms and molecules are also involved, including those leading to the muscle-specific fusion of plasma membranes to form myotubes.

We conclude that N-CAM (or a similar molecule) is present on the plasma membrane of developing skeletal muscle cells, and that nerve cells can bind to muscle cells via the calcium-independent[13] adhesion mechanism involving N-CAM. The presence of N-CAM on a cell type of mesenchymal origin as well as in ectodermally derived nerve tissue raises the possibility that N-CAM expression on cells is more a reflection of functions required for morphogenesis than of cell lineage. In view of this possibility, it will be of particular interest to test for the presence and localization of N-CAM in embryos at earlier stages of development.

Table 1 Binding of neural and muscle cells to retinal nerve cell monolayers

Cell binding to monolayer	F(ab′) present during binding*	No. of cells bound to monolayer (1 mm^2)	% Inhibition by anti-N-CAM F(ab′)
Myoblasts	Nonimmune	174	—
Myoblasts	Anti-N-CAM	64	63
Retinal neurones	Nonimmune	389	—
Retinal neurones	Anti-N-CAM	105	73
Fibroblasts	—	30	—

Myoblasts and retinal nerve cells were prepared as described in Fig. 2 legend. Fibroblasts were dissociated from skin of 11-day chick embryos with 0.1% trypsin and grown in Dulbecco's modified Eagle's medium containing 10% fetal calf serum. At confluence, fibroblasts were removed from culture dishes with trypsin, cultured in suspension for 4 h and internally labelled with diacetyl fluorescein. As described previously[10], monolayers of retinal cells were prepared on waxbean agglutinin-coated 35-mm culture dishes, incubated for 20 min at 25 °C with a suspension of cells internally labelled with fluorescein and scored for binding by fluorescence microscopy. Retinal nerve cells in suspension also bound to monolayers of myoblasts or myotubes, but only ~20% of this binding was inhibited by anti-N-CAM F(ab′). We have previously observed that inhibition of heterotypic binding by F(ab′) is sometimes affected when the cell types in the suspension and monolayer are reversed[13]. Although the cause of this effect is not understood, binding of vesicles to myotubes in monolayers or to myoblasts in suspension was strongly inhibited by F(ab′) (Table 2).

*20 μg ml^{-1} of affinity-purified F(ab′) or nonimmune F(ab′) were added to the incubation medium.

Table 2 Binding of vesicles containing N-CAM to cells

Cells	Source of vesicles	% Of cells binding vesicles With nonimmune F(ab′)	With anti-N-CAM F(ab′)
Myoblasts*	Brain tissue	69	18
Retinal neurones	Brain tissue	75	26
Fibroblasts	Brain tissue	0	—
Myoblasts	N-CAM + lipid	60	5
Myoblasts	Lipid	6	—

Myoblasts and retinal nerve cells were prepared as for Fig. 2, and fibroblasts as for Table 1, except without the internal fluorescent label. Vesicles containing N-CAM and carboxyfluorescein were isolated as described in Fig. 3 legend, and lipid vesicles were prepared as described but in the absence of N-CAM. Binding was scored by fluorescence microscopy (see Fig. 3 legend) after incubating 20 μl of vesicles with 5×10^6 cells in 1 ml SME medium for 20 min at 37 °C in the presence of 10 μg ml^{-1} of F(ab′).

*60–70% of cells scored were myoblasts[14].

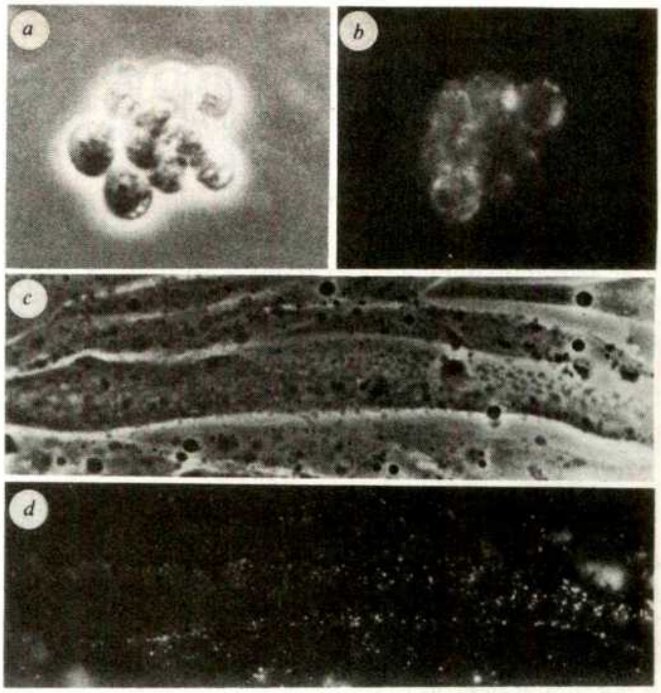

Fig. 3 Binding of brain tissue vesicles to myoblasts (*a*, *b*), and binding of reconstituted vesicles containing lipid and affinity-purified N-CAM to myotubes (*c*, *d*). *a* And *c* are phase contrast micrographs at ×570 and ×375 respectively; *b* and *d* are fluorescence micrographs of the same fields. Myoblasts were prepared as described in Fig. 2 legend, and myotubes as described in Fig. 1 legend. Fluorescent N-CAM vesicles were prepared by removal of detergent from a solution containing 6 mg ml^{-1} of lipids extracted from chick brain, 0.2 mg ml^{-1} of affinity-purified N-CAM and 5 mg ml^{-1} 6-carboxyfluorescein[5]. Membrane vesicles were prepared from 14-day embryo brains by homogenization of the tissue in the presence of 5 mg ml^{-1} 6-carboxyfluorescein, isolated by sucrose density centrifugation and washed with phosphate-buffered saline. Binding of vesicles to cells was carried out by incubation of 20 μl of vesicles with 5×10^6 cells in SME medium in a 1-ml suspension, or with myotubes on coverslips for 20 min at 37 °C with gentle shaking. Unbound vesicles were removed by differential centrifugation of the myoblasts or washing of myotube monolayers.

Non-dopaminergic fibres may regulate dopamine-sensitive adenylate cyclase in the prefrontal cortex and nucleus accumbens

The dopaminergic (DA) innervation of the prefrontal cortex in rat originates from neurones distributed in the anterior medial part of the ventral tegmental area (VTA)[1]. Biochemical[2,3] and electrophysiological[4] studies have demonstrated that these mesocortico-prefrontal neurones are distinct from others located in the VTA which project to subcortical structures such as the nucleus accumbens. DA receptors coupled to an adenylate cyclase (D-1 receptors) are present in the prefrontal cortex and their topographical distribution closely resembles that of DA nerve terminals[5–7]. We have now further analysed the properties of the cortical D-1 receptors and compared them with those of a subcortical limbic structure examining, in the rat, the effects on DA-sensitive adenylate cyclase activity in the prefrontal cortex and the nucleus accumbens of (1) bilateral 6-hydroxydopamine (6-OHDA) microinjections in the VTA and (2) bilateral electrolytic lesions of the VTA. The results suggest that regulation of D-1 receptors is not solely dependent on the presynaptic DA innervation and that other non-DA fibres may contribute to it.

Male Sprague–Dawley rats (180–250 g) were lesioned bilaterally in the VTA either by 6-OHDA (4 μg in 1 μl) microinjections or by electrocoagulation as described previously[8,9]. In some cases, animals were pretreated with desipramine (DMI; 25 mg per kg intraperitoneally, i.p.) 30 min before the 6-OHDA microinjections. Sham-operated rats were used as controls. All animals were killed between 11 a.m. and 1 p.m., 40–60 days after the lesions. Brains were rapidly removed, their rostral halves fixed with sodium chloride (0.9%) on a Leitz Kryomat[10] and caudal parts kept for histological control. Using cylindrical tubes (1.4 and 0.9 mm diameter for the prefrontal cortex and the nucleus accumbens respectively), microdisks of tissues were punched out bilaterally on successive 500-μm-thick coronal slices from the ventral part of the prefrontal cortex[7] (planes 11,300 and 10,800 μm according to the atlas of König and Klippel[11]; four microdisks; 310 μg protein) or the nucleus accumbens (planes 9,600 and 9,100 μm; six microdisks; 190 μg protein). Tissues from individual animals were then treated to estimate DA-sensitive adenylate cyclase activity as previously described (refs 6, 7; Fig. 2 legend), and DA and noradrenaline levels in each sample were determined radioenzymatically[12].

As expected, a marked decrease in DA levels was observed in both the prefrontal cortex and the nucleus accumbens in rats with bilateral 6-OHDA lesions (Fig. 1). However, surprisingly, there was no change in the DA-sensitive adenylate cyclase activity in these structures despite the nearly complete destruction of their DA innervation (Fig. 1).

Similarly, in most of the animals with bilateral electrolytic lesions (10 out of the 14 lesioned rats) there was a significant reduction of DA levels in both the prefrontal cortex and the nucleus accumbens. In these rats, the DA-sensitive adenylate cyclase activity was significantly increased in the prefrontal cortex (+62 ± 6%; Fig. 1) when compared with results obtained in corresponding sham-operated animals. This effect resulted from an increase in the maximal DA stimulation and not from a change in the apparent affinity of DA for its receptor, suggesting that the number of D-1 receptors coupled to the adenylate cyclase was enhanced (Fig. 2). In contrast, at a DA concentration (10^{-4} M) which induced the effect in the prefrontal cortex, no significant change in the DA-sensitive adenylate cyclase activity was observed in the nucleus accumbens (Fig. 1). This lack of effect was even seen in three animals in which the electrolytic lesions reduced DA levels by >95% (data not shown). These results seem to contradict those of Rosenfeld *et al.*[13] who reported that unilateral electrolytic lesion of the VTA increases the DA-sensitive adenylate cyclase activity in the ipsilateral nucleus accumbens. However, they did not take into account the presence of high levels of DA in nucleus accumbens homogenates from the non-lesioned side. Indeed, a Lineweaver–Burk plot of their data reveals a difference in the affinity but no change in the maximal stimulation of the DA-sensitive adenylate cyclase activity in the denervated nucleus accumbens.

The difference in the effects of the 6-OHDA and electrolytic lesions on cortical noradrenergic (NA) levels might help to explain the lack of development of supersensitivity of the cortical D-1 receptors in the 6-OHDA lesioned rats. Indeed, in most cases, electrolytic VTA lesions did not destroy the ascending NA fibres projecting to the prefrontal cortex (Table 1). On the contrary, probably due to the neurotoxin diffusion, 6-OHDA microinjections also severely affected all ascending fibres of the NA dorsal bundle which pass near the VTA (Table 1). In another experiment designed to test further the eventual

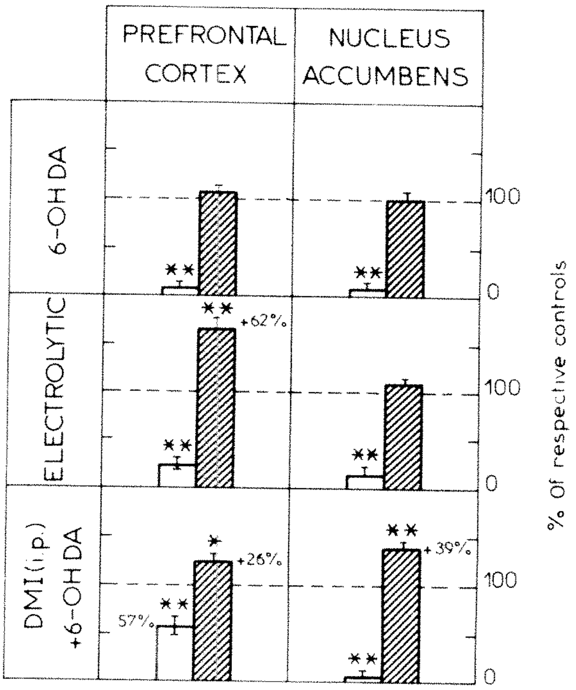

Fig. 1 Effects of different VTA lesions on DA levels and DA-sensitive adenylate cyclase activity in the prefrontal cortex and the nucleus accumbens. Rats were killed 40–60 days after each type of lesion and microdisks of tissue were punched out from the prefrontal cortex and the nucleus accumbens. After homogenization aliquots were taken for the estimation of DA levels and DA-sensitive adenylate cyclase activity. Results are the mean ±s.e.m. of data obtained with groups of 5–10 rats. Mean values ±s.e.m. of sham-operated animals were, respectively, in the prefrontal cortex and the nucleus accumbens: DA levels, 1.2 ± 0.1 and 75 ± 6 ng per mg protein; basal adenylate cyclase activities, 32 ± 1 and 38 ± 2 pmoles cyclic AMP per min per mg protein; DA (10^{-4} M)-stimulated adenylate cyclase activity, 63 ± 3 and 151 ± 12 pmoles cyclic AMP per min per mg protein. The basal adenylate cyclase activity in the lesioned animals was not affected in either the prefrontal cortex or the nucleus accumbens. $* P < 0.05$ and $** P < 0.01$ (Student's *t*-test) when compared with respective values obtained in sham-operated animals. □, DA levels; ▨, DA-sensitive adenylate cyclase activity.

0028-0836/82/080696—03$01.00

Table 1 Effects of different VTA lesions on NA levels in the prefrontal cortex

VTA lesion	Noradrenaline (ng per mg protein)	% Change compared with control
Sham	2.80 ± 0.20 (10)	
6-OHDA	0.10 ± 0.05 (10)	−96*
Electrolytic	2.29 ± 0.25 (10)	−18
DMI (i.p.) + 6-OHDA	1.85 ± 0.19 (8)	−34†

Forty to sixty days after each type of VTA lesion, rats were killed and, after sampling and homogenization of the prefrontal cortex tissues, NA levels were estimated radioenzymatically[12]. Numbers in parentheses correspond to the size of each group. Values are mean ±s.e.m.

* $P < 0.001$ and † $P < 0.01$ when compared with sham-operated animals.

influence of the NA fibres on the regulation of cortical D-1 receptors, animals were treated with DMI before the microinjections of 6-OHDA in the VTA. As expected, this treatment markedly reduced the 6-OHDA neurotoxic effect on NA fibres but allowed the complete destruction of DA neurones projecting to the nucleus accumbens. Curiously, for an unknown reason, the cortical DA innervation was partially preserved because DA levels were only reduced by 43% in the prefrontal cortex. In these conditions, DA-sensitive adenylate cyclase activity was significantly increased in both the prefrontal cortex and the nucleus accumbens, the effect being more pronounced in the latter structure (Fig. 1).

A supersensitivity of D-1 receptors has already been shown in the striatum after electrolytically or 6-OHDA-induced degeneration of the nigro-striatal DA system[14,15]. The results reported here—the marked increase in the DA-sensitive adenylate cyclase activity in the prefrontal cortex after electrolytic destruction of the mesocortico-prefrontal DA neurones—extend these observations. As already discussed, this effect probably results from an enhanced number of D-1 receptors. Its amplitude depends on the extent of DA denervation—in animals with electrolytic lesions a correlation was found between the increase in cortical DA-sensitive adenylate cyclase activity and the degree of the reduction in cortical DA levels (data not shown). It is thus not surprising that the increase in the cortical DA-sensitive adenylate cyclase activity was less pronounced after the partial destruction of the mesocortico-prefrontal DA neurones induced by the 6-OHDA lesion in DMI-pretreated rats. An interesting finding was that the presence of NA fibres seems necessary for the appearance of the increased cortical DA-sensitive adenylate cyclase activity; changes in the regulation of the cortical D-1 receptors were only seen when cortical NA fibres were only slightly or not affected by the lesion (electrolytic, 6-OHDA in DMI-pretreated rats). In contrast, in rats injected with 6-OHDA alone the concomitant destruction of the NA fibres prevented the increase in DA-sensitive adenylate cyclase activity despite the pronounced degeneration of the DA neurones innervating the prefrontal cortex. It is therefore possible that the cortical NA fibres exert a permissive role on the development of the cortical D-1 receptors supersensitivity. Of relevance in this context is the observation that there is a population of cells in the rat prefrontal cortex which responds to both DA and NA[16].

Because NA accounts for ~2% of DA levels in the nucleus accumbens, it was not possible to estimate precisely the effect of 6-OHDA lesions on NA levels in this structure. However, changes in cortical NA levels can be used as an index of the destruction of ascending NA fibres which pass near or through the nucleus accumbens. In any case the development of the D-1 receptors' supersensitivity in the nucleus accumbens does not seem to depend on the presence of ascending NA fibres as there was no change in DA-sensitive adenylate cyclase activity in this structure either when NA fibres were not destroyed (electrolytic lesion) or when they were markedly affected (6-OHDA lesions). Although all types of lesion made induced a pronounced degeneration of the nucleus accumbens DA innervation, the only one which resulted in a significant increase in the DA-sensitive adenylate cyclase activity in this structure was the 6-OHDA lesion made in DMI-pretreated rats. As this lesion was also the only one which partially prevented the destruction of the mesocortico-prefrontal DA neurones, we suggest that the presence of the mesocortico-prefrontal DA neurones is required for the development of D-1 receptors supersensitivity in the DA-denervated nucleus accumbens. Neurones originating in the prefrontal cortex are known to project into the nucleus accumbens[17], and Pycock *et al.*[18] have recently shown that the specific destruction of DA terminals in the prefrontal cortex induced several biochemical changes in various subcortical structures, including an enhanced rate of DA utilization in the nucleus accumbens and the striatum. By their effect on cortical efferent pathways, the mesocortico-prefrontal DA neurons may contribute not only to the regulation of DA transmission in subcortical structures such as the nucleus accumbens, but also to the control of the activity of the target cells on which D-1 receptors are located. In other words, changes in the activity of cortical neurones projecting to the nucleus accumbens could be involved in the regulation of the DA-sensitive adenylate cyclase activity in this structure.

Several electrophysiological studies have demonstrated that the sensitivity of a receptor for a given transmitter can be modified by the action of another transmitter on the same cell[19,20]. Moreover, sustained changes in cell responsiveness to non-monoaminergic transmitters have been shown after denervation of monoaminergic systems in the central nervous system[21]. Our biochemical results provide a novel example of a regulatory process which could intervene in the control of receptor sensitivity: we have shown that the expected increase in the DA-sensitive adenylate cyclase activity after DA denervation can be modulated or even prevented in situations in

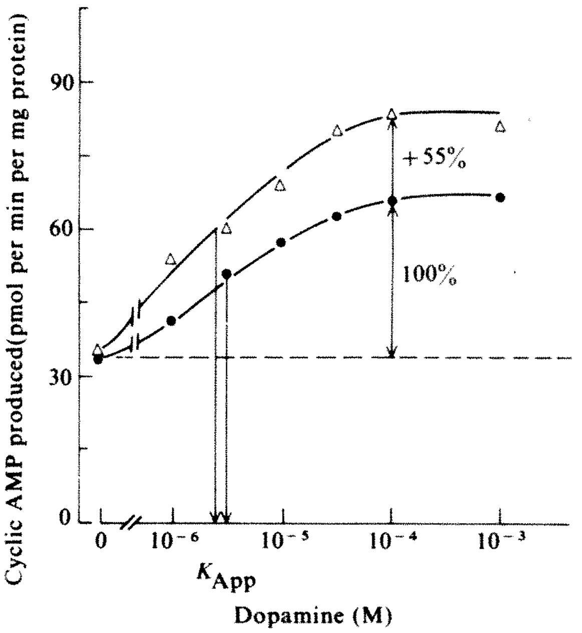

Fig. 2 Effect of bilateral electrolytic lesions of the VTA on the activity of the DA-sensitive adenylate cyclase in the prefrontal cortex. Eight microdisks of tissue (1.4 mm diameter) were punched out bilaterally in the ventral part of the frontal cortex[7] (11,300 μm and 10,800 μm slices following the atlas of König and Klippel[11]). Samples were homogenized in 200 μl of a 2 mM Tris-maleate, *p*H 7.2, 2 mM EGTA, 300 mM sucrose solution. Aliquots were taken to measure DA-sensitive adenylate cyclase activity[6,7] and to estimate dopamine and noradrenaline levels[12]. Each point corresponds to the mean of three determinations; extreme values did not differ by >5%. Variation of values obtained in 10 different sham-operated animals were within 8%. △, Electrolytic VTA lesion; ●, control.

which the target cells are simultaneously deprived or exposed to other significant signals. Such mechanisms may explain the variations observed[14,15,22] in receptor supersensitivity, which may depend on the selectivity of the procedure used to destroy the afferent fibres. Although further evidence is required for such regulation of receptor sensitivity, the phenomenon may be functionally significant and should be taken into consideration when evaluating the efficacy of a given transmission.

Importance of amino acid uptake and decarboxylation in gastrin release from isolated G cells

Lenard M. Lichtenberger, Remi Delansorne & Lynne A. Graziani

Department of Physiology and Cell Biology, University of Texas Medical School at Houston, Houston, Texas 77025, USA

Studies of various species have demonstrated that the post-prandial rise in serum gastrin levels is primarily attributable to the proteinaceous substances ingested[1-5]. Although it is generally assumed that dietary amino acids are the primary stimulants of gastrin release, evidence supporting this notion based on experiments *in vivo* has been conflicting and unconvincing[6-10]. We have investigated the role of amino acids as stimulants of gastrin release using a preparation of isolated rodent gastrin-containing G cells[11,12]. We report here that the ability of an amino acid to stimulate gastrin release *in vitro* is directly correlated with its lipid solubility, the aromatic and long chain aliphatic amino acids being the most potent. In addition, we provide evidence that amino acid decarboxylation may be a necessary step in gastrin release as inhibitors of decarboxylase activity abolished amino acid-induced gastrin release, and amines, the decarboxylated derivatives of amino acids, were potent stimulants of hormone secretion *in vitro*. Thus, the uptake and decarboxylation of amine precursors may be a functionally important property of cells belonging to the APUD (amine precursor uptake and decarboxylation) class of endocrine cells.

We investigated the effects of amino acids and their metabolites on gastrin release *in vitro* using a preparation of enriched G cells isolated according to a modification of a procedure described elsewhere[11,12] (see Fig. 1 legend). Initially we compared the ability of various amino acids to stimulate gastrin release *in vitro*. We included one or more of the amino acids from each of the major classes. The results (see Table 1) indicate that both charged amino acid residues and simple neutral aliphatic amino acid residues having a 1–3 carbon backbone failed to induce gastrin release from isolated G cells. In contrast, the more nonpolar molecules, the aliphatic amino acids having four or more carbon atoms, and the aromatic amino acids, stimulated gastrin release into the medium.

The effectiveness of an amino acid in stimulating gastrin release correlated significantly ($r < 0.001$) with the relative hydrophobicity of its side chain (Fig. 1). This relationship between the lipid solubility of an amino acid and its efficacy in stimulating gastrin release *in vitro* suggests that hormone secretion may depend on the ability of the amino acid to diffuse from the lumen into the interior of the G cell. This notion is supported by reports that amino acids and related compounds are transported into the gastric epithelium by a passive transport process[13]. The intracellular mechanism by which amino acid uptake is coupled to gastrin secretion, however, has yet to be characterized.

Table 1 Effect of amino acids and amines on gastrin release *in vitro*

Amino acids $NH_2\text{–}\overset{\overset{R}{\vert}}{C}H\text{–}COOH$	Gastrin release (% basal)	Amines $NH_2\text{–}\overset{\overset{R}{\vert}}{C}H_2$	Gastrin release (% of basal)

Proline	143 ± 24(4)		

An isolated and enriched preparation of rodent antral G cells was prepared using a modification of a procedure described elsewhere[11,12]. Strips of antral tissue were incubated for 90 min in enriched KRB (Krebs-Ringer bicarbonate) buffer containing pronase E(0.125%; EM Laboratories,) with shaking in water bath at 37 °C in an atmosphere of 95% O_2/5% CO_2 at 105 cycles min^{-1}. At the end of this period the remaining tissue was vigorously shaken by hand (~2,000 cycles min^{-1}) in pronase-containing medium, and then lightly scraped with a glass slide. This combination of selective pronase digestion followed by high shearing forces results in the removal of cells from the basal elements of the antral gland. The exfoliated cells and tissue were then incubated in enriched KRB buffer containing 20 $\mu g\ ml^{-1}$ of DNase I for 30 min, followed by gentle filtration (70 μm pore size) to disrupt the cell aggregates. The resulting cell suspension was washed several times in fresh enzyme-free KRB, and counted using a haemocytometer. Gastrin secretory testing was initiated by injecting the cells ($50\text{–}150 \times 10^3$ per tube) into a siliconized tube containing amino acid-free KRB with and without (control) the test agent. All test agents were used at a final concentration of 10 mM. The cells were incubated with shaking in a water bath at 37 °C in an atmosphere of 95% O_2/5% CO_2 for 10 min. The cells and medium were separated by filtration, and the filtrate was heat extracted at 96 °C for 10 min (ref. 2). The medium samples were then stored at −20 °C before radioimmunoassay of the medium gastrin concentration. Gastrin concentration was determined by a modification of the technique of Yalow and Berson[19]. Purified human gastrin G-17 I was iodinated by the chloramine T method and purified by the method of Stadil and Rehfeld[20]. Antibody 1296, which recognizes all known molecular forms of gastrin[21], was used in all assays. Numbers in parentheses are number of tubes per group.

* Represents a statistically significant difference ($P < 0.05$) compared with medium gastrin concentration of cells incubated in control medium.

† Represents a statistically significant difference ($P < 0.05$) compared with medium gastrin concentration for cells incubated in medium containing the respective amino acid (carboxylated derivative of the amine).

0028-0836/82/080698—03$01.00

Pearse initially proposed the APUD hypothesis[14]. He demonstrated that many endocrine cells, like neural tissue, are able to decarboxylate amine precursors to form the parent amine. Many endocrine cells of the gastrointestinal tract, including the G cell, have been demonstrated histochemically to be members of the APUD family of endocrine cells. Although the importance of the decarboxylase enzymes has been established neurophysiologically, their functional role in endocrine cells remains to be elucidated fully.

We have also demonstrated (see Table 1) that many amines, products of amino acid decarboxylation, are highly efficient in stimulating gastrin release *in vitro*. Note that without exception, amines induced a greater stimulation of hormone secretion than the respective amino acids from which they are derived. These findings are not totally unexpected as previous studies have demonstrated that certain aromatic and aliphatic amines (the catecholamines and cysteamine) are potent stimulants of gastrin release *in vivo*[23-25]. Subsequent experiments have indicated that certain biogenic amines, (serotonin, histamine, spermine and taurine) are unable to stimulate gastrin release *in vitro*. These results suggest that amine-stimulated gastrin release is not a nonspecific G cell response to amines in general, but is a specific response to certain molecular species of this class of compounds.

We then investigated whether the ability of an amino acid to stimulate gastrin release *in vitro* could be modulated in parallel with the decarboxylase activity of the endocrine cell. To test this possibility, glandular cells of the antrum were incubated in medium containing the stimulatory aromatic amino acid, phenylalanine, with or without the addition of the decarboxylase inhibitors, α-methyl-L-dopa (specific L-aromatic amino acid decarboxylase inhibitor), 4-deoxypyridoxine and aminooxyacetic acid (nonspecific decarboxylase inhibitors)[15,16]. Subsequent studies revealed that all three agents significantly reduced the L-aromatic amino acid decarboxylase activity of isolated intact antral glandular cells when [1-alanine-^{14}C]DL-dopa was used as substrate (unpublished results). Figure 2 shows that all three inhibitors significantly blocked phenylalanine-induced gastrin release. In addition, this abolition of amino acid-induced hormone release could not be attributed to a general depression of cell function, as the decarboxylated derivative of phenylalanine, methylbenzylamine, was still capable of stimulating gastrin release in the presence of deoxypyridoxine. Note also that subsequent experiments demonstrated that these inhibitors of cellular decarboxylase activity had minimal affect on basal gastrin release, and effectively abolished the stimulatory actions of other aromatic amino acids (such as tryptophan) on gastrin release *in vitro*.

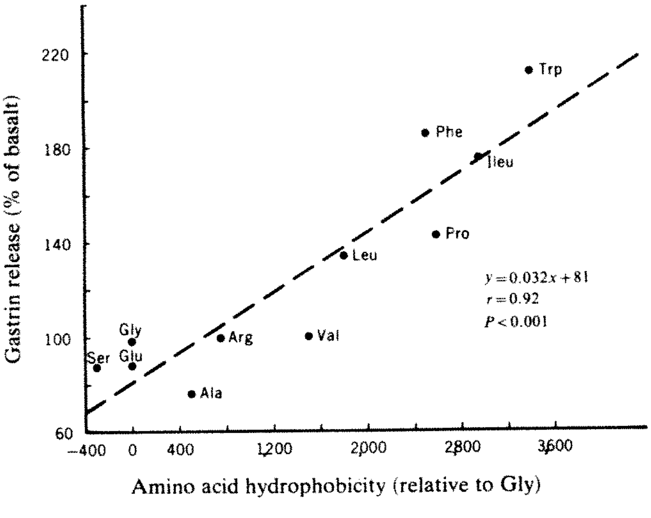

Fig. 1 Relationship between the ability of an amino acid to stimulate gastrin release *in vitro* and the hydrophobic properties of its side chain. The data points were limited to those amino acids whose relative hydrophobicity were estimated by Bigelow and Channon[22]. There is a statistically significant linear relationship between the two properties ($r = 0.92$; $P < 0.001$).

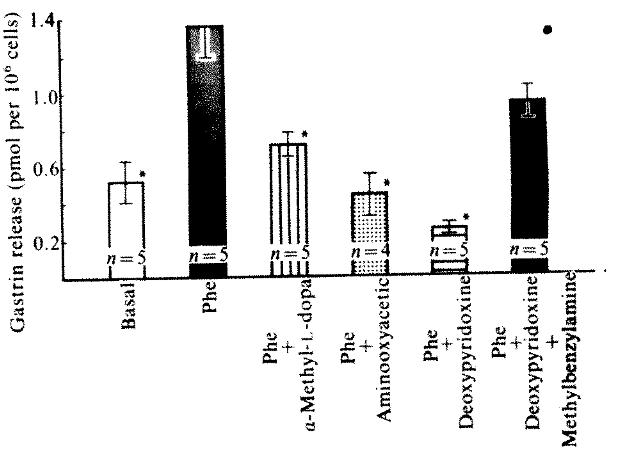

Fig. 2 Effect of decarboxylase inhibitors on phenylalanine-induced gastrin release *in vitro*. The isolated and enriched G cells were prepared and studied as described in Table 1 legend. In addition to cells incubated in amino acid-free KRB alone (basal), cells were incubated in phenylalanine-containing medium (10 mM) in the absence and presence of the following inhibitors of decarboxylase activity: α-methyl-L-DOPA (0.01 mM); aminooxyacetic acid (1 mM); 4-deoxypyridoxine (1 mM) alone, and together with the stimulatory amine, methylbenzylamine (10 mM). * Represents a statistically significant difference ($P < 0.05$) compared with the medium gastrin levels of cells incubated with phenylalanine alone. † Represents a statistically significant difference ($P < 0.001$) compared with the medium gastrin levels of cells incubated with phenylalanine and deoxypyridoxine.

These results suggest that gastrin release, which is triggered by the ingestion of a meal containing protein, may depend in part on the passive transport of amino acids into the G cell, followed by their intracellular decarboxylation. This notion is further supported by autoradiographic evidence[17,18] that the DOPA decarboxylase activity of the G cell resides anatomically in close proximity to the gastrin-containing secretory granules. However, the mechanism by which the amine product is coupled to hormone release remains to be determined. Further experiments will ascertain whether the decarboxylase enzymes have a similar role in mediating the amino acid-induced release of hormones from other endocrine cells possessing the APUD facility.

We thank Mr William Vargo for technical assistance and Drs Morton I. Grossman and John H. Walsh (CURE) for donating purified human gastrin G-171 and antibody 1296 which were used in the radioimmunoassays. This work was supported by NIH grant AM 20686. R.D. performed this work as a visiting student from Ecole Nationale Veterinaire D'Alfort.

Inhibition of spindle elongation in permeabilized mitotic cells by erythro-9-[3-(2-hydroxynonyl)] adenine

W. Zacheus Cande

Department of Botany, University of California, Berkeley,
California 94720, USA

Studies using living cells[1,2] and experimental manipulation of permeabilized mitotic cells[3,4] demonstrate that the movement of anaphase chromosomes consists of two physiologically distinct events: chromosome movement to the spindle poles (anaphase A) and separation of the poles via spindle elongation (anaphase B). Shortening of kinetochore-attached microtubules is associated with anaphase A and rearrangement and lengthening of the polar microtubules, especially those found in the spindle midzone, with anaphase B[5,6]. It has been suggested that interactions between microtubules, mediated by dynein-like cross-bridges similar to those found in flagella, may be the mechanochemical system responsible for anaphases A and B[7,8]. Recently Bouchard *et al.*[9] have demonstrated that erythro-9-[3-(2-hydroxynonyl)]adenine (EHNA), a protein carboxylmethylation inhibitor, is a specific inhibitor of flagellar beat and dynein ATPase activity. I have now investigated the possibility that dynein-like ATPases have a role in anaphase by adding EHNA to permeabilized cell models in conditions compatible with maintenance of anaphases A and B after lysis[3,4]. I find that EHNA blocks anaphase B but not anaphase A. These results are consistent with the involvement of a dynein-like ATPase in spindle elongation.

Mitotic PtK_1 cells (a kidney epithelial line derived from the rat kangaroo) continue to undergo anaphase after permeabilization of the cell with the nonionic detergent Brij 58 (Fig. 1, step 1, and ref. 3) provided polyethylene glycol is added to the medium 1–2 min after lysis (Fig. 1, step 2). After lysis the dividing cells are permeable to ions, nucleotides, dyes and proteins[3,4]. The rate and extent of spindle elongation (Fig. 1*a*, ●) in lysed mitotic cells depend on the ATP concentration in the medium[4]. In contrast, chromosome-to-pole movement in the permeabilized cell (Fig. 1*a*, △) does not require Mg^{2+}-ATP and is not affected by the presence of sulphydryl reagents, vanadate (a flagellar dynein ATPase inhibitor) and non-hydrolysable ATP analogues in the lysis medium[4].

EHNA, at concentrations that block movement of native rat and sea urchin spermatozoa[9], does not block anaphase when added to intact PtK_1 cells during prometaphase.

After lysis, EHNA preferentially blocks spindle elongation in dividing cells (Fig. 1*b*, Table 1) but does not reduce the rate of chromosome-to-pole movement. Inhibition of anaphase B by EHNA can be prevented by increasing the level of ATP in the lysis medium (Table 1). This result is consistent with the observation that EHNA is a weak mixed competitive inhibitor of dynein ATPase activity[9]. The relative concentration of EHNA required for 75% inhibition of anaphase B (0.2 mM ATP, 0.5 mM EHNA; Table 1) is similar to that required for 50% inhibition of dynein ATPase activity (0.1 mM ATP, 0.23 mM EHNA)[9] and reactivation of demembranated sea urchin spermatozoa (0.2 mM ATP, ~0.75 mM EHNA)[9].

Table 1 Effect of EHNA on chromosome movement

Treatment	No. of experiments	Rates of movement (μm min^{-1}) Chromosome separation	Spindle elongation	Chromosome-to-pole movement
0.2 mM ATP	14	0.55±0.15	0.26±0.10	0.15±0.07
+0.1 mM EHNA	6	0.55±0.16	0.19±0.14	0.18±0.05
+0.5 mM EHNA	9	0.46±0.15	0.06±0.10	0.19±0.06
+2.0 mM EHNA	13	0.32±0.11	0.04±0.06	0.14±0.05
+2.0 mM EHNA and 1.25 mM ATP	5	0.59±0.14	0.33±0.06	0.14±0.04

Rates of movement were estimated by measuring the slopes of the graphs (Fig. 1) of chromosome–chromosome and pole–pole distances from the moment of addition of the step 2 medium (see Fig. 1 legend) to the position of maximum displacement of chromosomes or poles. The rate of chromosome-to-pole movement was calculated as one-half the difference between the rates of chromosome separation and spindle elongation[3]. Values are given with standard deviations.

EHNA was originally described as a potent inhibitor of protein carboxylmethylation because it increases the intracellular concentration of *S*-adenosyl-L-homocysteine through inhibition of adenosine deaminase[9–11]. To study whether EHNA blocked anaphase by this mechanism, PtK_1 cells were lysed in *S*-adenosyl-L-homocysteine, adenosine and cycloleucine, which are known to inhibit protein carboxylmethylation[9–11], and in *S*-adenosyl-L-methionine, a donor of methyl groups[11]. As *S*-adenosyl-L-homocysteine and adenosine are almost as effective as EHNA in retarding spindle elongation (Table 2), we cannot rule out the possibility that protein carboxylmethylation is somehow involved in this process. However, the concentration of these drugs required to inhibit anaphase B are 10^2–10^3-fold higher than that required to inhibit protein carboxylmethylation *in vivo* or *in vitro*[9–11]. Cycloleucine, another inhibitor, does not block anaphase B (Table 2), and *S*-adenosyl-L-methionine, which should promote protein carboxylmethylation *in vitro*, inhibits anaphase B (Table 2) in the permeabilized cell. In addition, inhibition of spindle elongation by EHNA and adenosine depends on the ATP concentration in the lysis medium (Tables 1, 2). These results suggest that EHNA, *S*-adenosyl-L-homocysteine and adenosine all inhibit spindle elongation due to a common property other than their ability to inhibit protein carboxylmethylation. In this regard, spindle elongation differs from flagellar movement, because dynein ATPase activity and flagellar beat are not inhibited by adenosine[9].

It has been suggested that actomyosin may help to generate the forces required for anaphase chromosome movement[12]. As described previously[13], skeletal myosin ATPase activity is unaffected by millimolar concentrations of EHNA, and glycerinated myofibril contraction continues in concentrations of ATP and EHNA that block anaphase B (W.Z.C., unpublished data). To study the effect of EHNA on a process in lysed cells known to involve actomyosin, 1–2 mM EHNA was added to permeabilized PtK_1 cells undergoing cytokinesis. Cleavage furrow constriction continues for several minutes after lysis using

Table 2 Effect of carboxyl transmethylation inhibitors on chromosome movement

Treatment	No. of experiments	Rates of movement (μm min^{-1}) Chromosome separation	Spindle elongation	Chromosome-to-pole movement
0.2 mM ATP	5	0.56±0.08	0.24±0.09	0.16±0.02
+0.5 mM *S*-adenosyl-L-homocysteine	5	0.37±0.15	0.11±0.16	0.13±0.03
+0.5 mM *S*-adenosyl-L-methionine	5	0.43±0.10	0.09±0.08	0.18±0.06
+12 mM cycloleucine	5	0.61±0.10	0.21±0.11	0.19±0.06
+0.5 mM adenosine	5	0.39±0.09	0.14±0.16	0.13±0.04
+2.0 mM adenosine and 1.25 mM ATP	3	0.62±0.20	0.33±0.12	0.15±0.04

0028-0836/82/080700—02$01.00

the procedure described in Fig. 1 legend (see ref. 3) and EHNA does not alter the rate or extent of cleavage (W.Z.C., unpublished data).

As microtubule polymerization may have a role in spindle elongation (reviewed in refs 2, 5), the effect of EHNA on *in vitro* polymerization of neurotubulin was followed spectrophotometrically by monitoring changes in turbidity[14]. Extracts containing 3–5 mg ml^{-1} twice-cycled neurotubulin[3] were warmed to 37 °C in medium containing 100 mM PIPES, *p*H 6.94, 1 mM $MgSO_4$, 1 mM EGTA and either 0.5 mM GTP and 2 mM EHNA or 1 mM GTP and 5 mM EHNA. No change in rate or extent of microtubule polymerization in the presence of four- to fivefold more EHNA than nucleotide was detected.

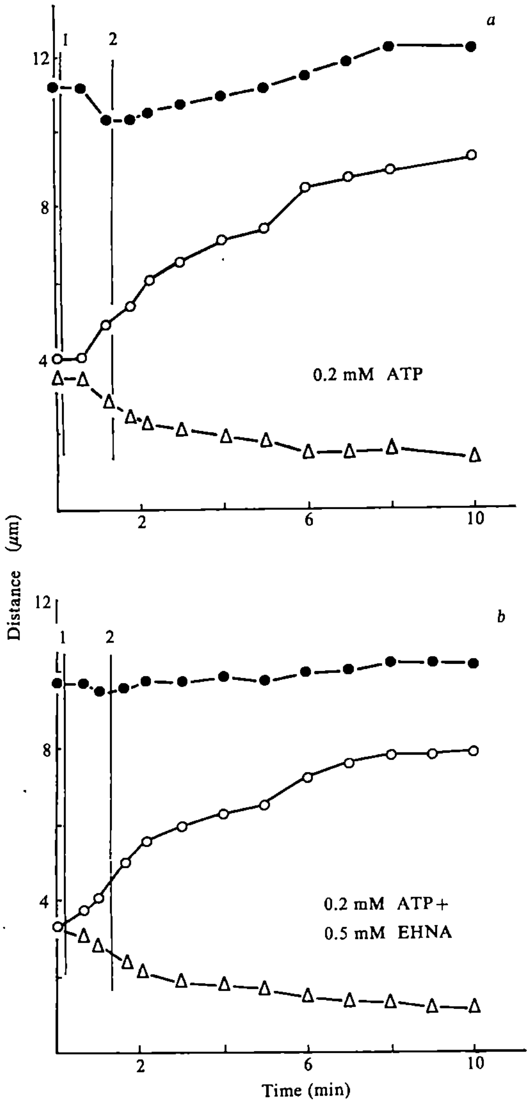

Fig. 1 Effect of EHNA on chromosome movements in permeabilized cells. Separation of spindle poles (●), sister chromatids (○) and chromosome-to-pole movement in one half spindle (△) when cells are lysed in a medium containing 0.2 mM ATP (*a*) or 0.2 mM ATP and 0.5 mM EHNA (*b*). PtK$_1$ cells were used in all experiments and were maintained and handled for light microscopy as described in ref. 3. Coverslips were mounted on slides with coverslip fragments as spacers. Anaphase cells were lysed by flushing solutions under the coverslip in a two-step lysis procedure: step 1 medium contained 85 mM PIPES, 0.08% Brij 58, equimillimolar nucleotide or EHNA (Burroughs-Wellcome) and $MgSO_4$, 10^{-7} M free Ca^{2+} and 1 mM free Mg^{2+}. Step 2, which followed 70–90 s after step 1, used a similar medium that included in addition 2.5% polyethylene glycol (molecular weight 20,000) and 0.1% Brij 58. The composition of the Ca^{2+}-EGTA buffer system was determined using a computer program provided by R. Steinhardt. Using a stability constant of 10.7 at *p*H 6.94 and 10 mM EGTA as a buffer, 1.51 mM $CaCl_2$ and 1.28 mM $MgSO_4$ were added to the lysis medium.

Thus EHNA inhibition of anaphase B is consistent with the argument that a dynein-like ATPase is responsible for generating the forces required for spindle elongation[7,8] and that anaphases A and B are physiologically distinct processes that can be uncoupled by the appropriate experimental manipulation[1,3,4].

I thank Susan Elliger for technical assistance, Carl Elliger and Kent McDonald for helpful discussions, and Steve Penningroth for preprints describing the specificity of EHNA inhibition of dynein ATPase activity and helpful discussions concerning the mechanism of EHNA inhibition. This research was supported by grants from NIH, American Cancer Society and the University of California Cancer Research Coordinating Committee.

Inhibitors of dynein activity block intracellular transport in erythrophores

Mary C. Beckerle & Keith R. Porter

Department of Molecular, Cellular and Developmental Biology,
University of Colorado, Campus Box 347, Boulder,
Colorado 80309, USA

Erythrophores, cells capable of translocating pigment granules along a radially arrayed cytoskeletal framework, provide an excellent model system for studying intracellular particle transport. Numerous examples of intracellular motility are based on microtubules[1] and all available evidence indicates that organized pigment granule transport in erythrophores depends on these structures[2]. The best studied microtubule-based motility system is the flagellum. As it relies on a dynein–microtubule interaction to generate motive force[3], we have investigated the effects of dynein ATPase inhibitors on pigment granule transport. Vanadate is a potent inhibitor of dynein ATPase activity *in vitro*[4–6] and has been shown to inhibit microtubule-based motility in cilia[4], flagella[4] and the mitotic spindle[7]. Recently, another dynein inhibitor, erythro-9-3-(2-hydroxynonyl)adenine (EHNA), has been described[8]. We report here that both microinjected vanadate and exogenously applied EHNA block saltatory movement of pigment granules in isolated squirrelfish erythrophores. The vanadate and EHNA sensitivities of directed pigment motion suggest that a dynein-like molecule may be an essential component of the erythrophore intracellular motility system.

Erythrophores isolated from the scales of the squirrelfish (*Holocentrus ascensionis*) and cultured on glass coverslips retain their capacity to translocate pigment granules[9]. Mass aggregative movement of the pigment towards the cell centre is rapid and of uniform velocity, while dispersive radial movements are

0028-0836/82/080701—03$01.00

slow and faltering. When the cell is in the dispersed state, the granules shuttle to and fro in short radial jumps or 'saltations'[9,10].

Pressure microinjection[11] of erythrophores with $\sim 7 \times 10^{-14}$ l ($\sim$7% of the cell volume) of a 10% sucrose solution at *p*H 7, containing fluorescein isothiocyanate-labelled bovine serum albumin (5–10 mg ml^{-1}) results in an initial aggregation of the pigment followed, within 1 min, by a return of normal granule movements. In contrast, the saltatory intracellular motility of erythrophores is rapidly inhibited when the cells are injected with vanadate (>50 μM) in the V(V) oxidation state (Table 1). Microinjection of vanadate at a concentration of 250 μM causes the pigment granules to freeze transiently and then disperse slightly, perhaps because of vanadate enhancement of adenylate cyclase activity[12]; chromatophores characteristically respond to increased intracellular cyclic AMP by dispersing their pigment[13,14]. Once this initial dispersion has occurred, the shuttling of granules ceases, and the pigment will no longer aggregate, as it usually would, in response to touch by the microinjection needle. Adjacent cells which pulsed in synchrony with the experimental cell before injection will, however, respond by aggregating their pigment when the injected cell is touched (Fig. 1). This result suggests that the injected cell is receiving the stimulus to aggregate and is communicating it to nearby cells, but is incapable of translocating its own pigment in response to the stimulus. Erythrophores injected with 50 or 100 μM V(V) exhibit all the above characteristics except they can occasionally aggregate their pigment in response to touch by the micropipette. However, this aggregation is much slower than that in coupled or control cells and is generally less complete.

When the concentration of vanadate in the injection buffer is increased to 500 μM, a cell immediately adjacent to the injected cell often loses its ability to translocate pigment granules, but touching either of these incapacitated cells results in aggregation of other cells previously observed to be coupled to the injected cell. It seems likely that the excess vanadate is passing through the same junctions that serve to couple the cells electrically; the $H_2VO_4^-$ form of V(V) which exists in aqueous solution at neutral *p*H[12,15] should pass readily through gap junctions because it is both small and negatively charged. The fact that an uninjected cell is inhibited in its motility illustrates that the injection procedure itself is not responsible for the effects on granule movement noted here. Moreover, as depolarization of the cell membrane is probably the primary signal to aggregate the pigment[16], the immobilized, injected cell must remain alive in order to communicate the aggregation stimulus to adjacent cells.

When the concentration of injected vanadate is decreased to 10 μM, an intermediate inhibitory effect is observed. The pigment translocation ceases in 32% of the cells injected while the remainder are affected either transiently or not at all. If the concentration of injected material is decreased to 1 μM, all injected cells remain competent to move their pigment.

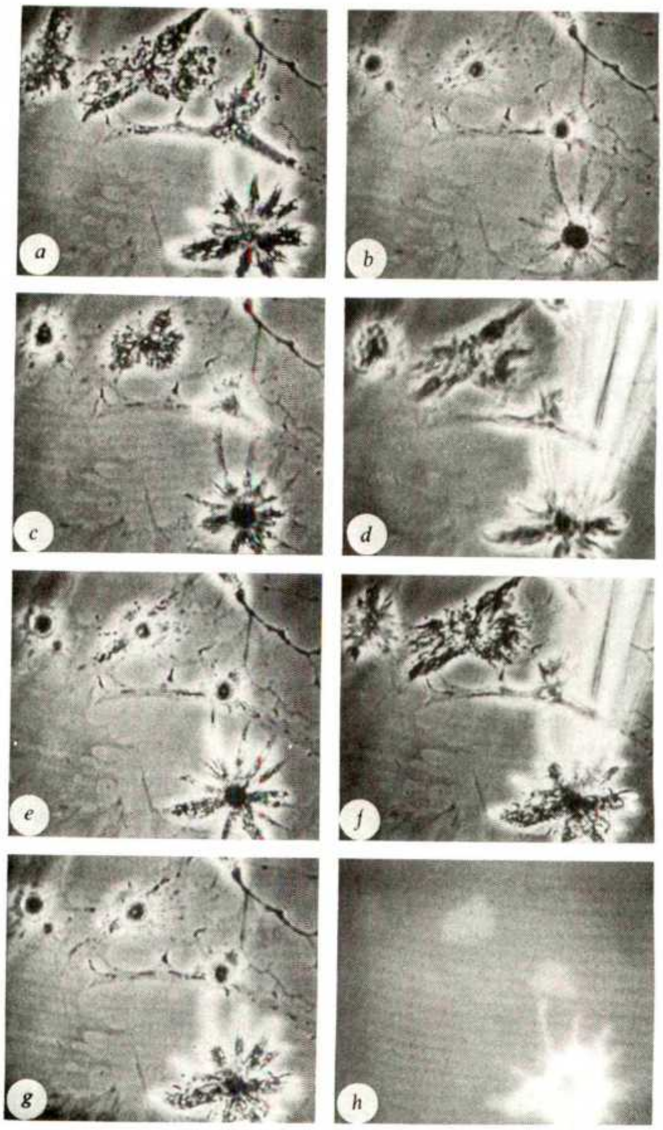

Fig. 1 Phase-contrast micrographs of four erythrophores in culture. The cells are coupled, that is, they disperse (*a*), aggregate (*b*) and redisperse (*c*) their pigment granules in synchrony. In *d*, the cells are in the dispersed state and one cell is microinjected with vanadate (250 μM) in injection buffer containing fluorescein-labelled bovine serum albumin. The injected cell is rapidly inhibited in its intracellular transport function whereas the three other cells continue to aggregate and disperse their pigment (*e*, *f*). Touching the microinjected cell with the micropipette (*f*) results in aggregation of the three coupled, uninjected cells, but the vanadate-injected cell does not respond to the stimulus with pigment movement (*g*). A fluorescence image (*h*) of the four cells illustrates that the cell on the lower right has been successfully injected. Slight autofluorescence of the pigment granules can be seen in the other erythrophores.

Kinetic analyses of the effect of vanadate on dynein *in vitro* have demonstrated that its inhibition of the ATPase activity is noncompetitive[5,6]. Vanadate inhibition of myosin[17] and the $(Na^+ + K^+)$ATPase[18,19], on the other hand, is competitive with substrate binding. Injection of a large excess of MgATP (up to 2.5 mM) together with 250 μM vanadate fails to prevent or slow the vanadate effects on pigment granule migration *in vivo*, suggesting that vanadate inhibition of granule motility is probably not due to an effect on any of the numerous ATPases[6] known to be competitively inhibited by vanadate.

Table 1 The effect of vanadate on pigment granule migration

Concentration of vanadate in micropipette (μM)	Approximate intracellular concentration* (μM)	No. of cells injected	Inhibition of transport (no. of cells; % inhibited)
500	37	55	55; 100
250	18.5	29	28; 97
100	7.3	21	21; 100
50	3.7	31	31; 100
10	0.73	22	7;32
1	0.073	42	0; 0

* Microinjection needles were calibrated by measuring the volume of oil droplets injected into erythrophores.

Incubation of erythrophores with another dynein inhibitor, EHNA, at a concentration of 4×10^{-3} M, in culture medium for 20 min also results in cessation of saltatory shuttling of pigment granules. At 10^{-3} M EHNA, a 60–90-min exposure is required before motility is inhibited. The dispersed cells appear to be frozen with regard to particle translocation. Although there is some brownian movement of the pigment granules, they do not shuttle and no spontaneous aggregation–dispersion cycles occur. Exogenous application of adrenaline stimulates the cells to aggregate their pigment granules, although the response is slowed relative to untreated cells.

EHNA has also been reported to inhibit protein carboxyl-methylase activity by increasing the intracellular concentration of *S*-adenosyl homocysteine[20]. In view of the fact that calcium appears to be the intracellular signal for aggregation of pigment granules[21] and calmodulin can be methylated[22], we examined the possibility that EHNA inhibition of pigment saltation was due to the inhibition of carboxyl-methylase rather than dynein ATPase. Microinjection of *S*-adenosyl homocysteine at concentrations up to 100 μM yielded no inhibition of pigment granule shuttling or aggregation and dispersion even after 60 min. As EHNA-induced inhibition of monocyte chemotaxis occurs rapidly when intracellular *S*-adenosyl homocysteine reaches $\sim 6\times 10^{-18}$ g per cell[20], the high concentration injected into erythrophores ($\sim 3\times 10^{-15}$ g per cell) should have readily inhibited pigment motion if it relied on carboxyl-methylase activity.

It seems unlikely that either vanadate or EHNA is simply interfering with the general ATP metabolism of the cells because co-injection of vanadate and ATP affects cells in the same manner as vanadate alone, and the cells treated with either vanadate or EHNA do not ultimately aggregate their pigment as do cells treated with various inhibitors of oxidative phosphorylation[10].

Dynein-like ATPase activity has been isolated from numerous microtubule-based motility systems, from sources as diverse as the sea urchin mitotic apparatus[23], *Saccinobaculus* axostyle[24] and human sperm[25]. Probes for dynein activity have been shown to inhibit anaphase chromosome movement[7,26], flagellar beat[4,8], microtubule-associated particle transport in fibroblasts[27] and, now, erythrophore pigment movement. Taken together these observations suggest that a dynein-like protein is a force-transducing molecule in microtubule-dependent intracellular motility in general.

This work was supported by a grant from the Muscular Dystrophy Association of America to K.R.P. and a Danforth Fellowship to M.C.B. M.C.B. thanks M. Zavortink for encouragement and instruction in microinjection and M. McNiven for care of the squirrelfish. We thank J. R. McIntosh and his team for many helpful discussions and generosity with equipment.

Cyclic AMP induces maturation of trout sperm axoneme to initiate motility

Masaaki Morisawa

Cyclic AMP has long been implicated as an activator of sperm motility[1–5]. From more recent experiments using demembranated mammalian and sea urchin spermatozoa[6,7], it was concluded that cyclic AMP only increases the motility of the axoneme after it has been initiated by MgATP^{2-}. We have now carried out similar experiments using spermatozoa collected from the rainbow trout and demembranated by treatment with the detergent Triton X-100. Our results suggest that in this species, cyclic AMP is required before MgATP^{2-} to trigger maturation of the nonmotile axoneme. Subsequent addition of an energy source then induces motility.

Semen was collected from mature rainbow trout, *Salmo gairdneri*, by inserting a pipette into the sperm duct. The plasma membrane and mitochondria of the sperm were then removed (confirmed in electron micrographs) by mixing at room temperature 1 volume of semen with 20 volumes of the extracting medium containing 0.15 M KCl, 0.5 mM MgSO$_4$, 5 mM CaCl$_2$, 0.5 mM EDTA, 1 mM dithiothreitol (DTT), 2 mM Tris buffer, *p*H 8.2, and 0.04% Triton X-100 for 30 s in the presence or absence of 0.5 mM cyclic AMP. Removal of the plasma membrane and mitochondria, elimination of the energy supply, and the dispersal of the components essential for axonemal movement in the extracting medium resulted in immotility of the axoneme. Reactivation of axonemal movement was then attempted using the modified method of Gibbons and Gibbons[8]: the demembranated sperm were resuspended in reactivating medium containing 0.15 M KCl, 2 mM MgSO$_4$, 0.5 mM CaCl$_2$, 2 mM EGTA, 1 mM DTT, 20 mM Tris buffer, *p*H 8.2, and 1 mM ATP again in the presence or absence of 0.5 mM cyclic AMP, and were observed by dark-field microscopy with stroboscopic mercury illumination at a magnification of ×200.

During demembranation rainbow trout spermatozoa remain quiescent due to the presence of K$^+$ in the seminal plasma[9] or KCl in the extracting medium. When cyclic AMP was absent from both the demembranating and reactivating media, no axonemal movement was observed (Fig. 1*a*). However, when the demembranated sperm were suspended in reactivating medium containing MgATP^{2-} and cyclic AMP, axonemal movement occurred (Fig. 1*b*), causing the reactivated sperm to swim at a speed of 103 ± 12 μm s^{-1} ($n = 8$). In contrast, motility of demembranated mammalian and sea urchin sperm is restored in the presence of MgATP^{2-}, with no requirement for cyclic AMP[6–8]. These results suggest that whereas the axoneme of mammalian and sea urchin sperm is already functionally mature and requires only an energy supply to initiate motility, the axoneme of rainbow trout sperm is functionally immature and is converted to the mature state by exposure to cyclic AMP.

When trout spermatozoa were demembranated in the extracting medium (always ATP free) containing cyclic AMP and then

0028–0836/82/080703—02$01.00

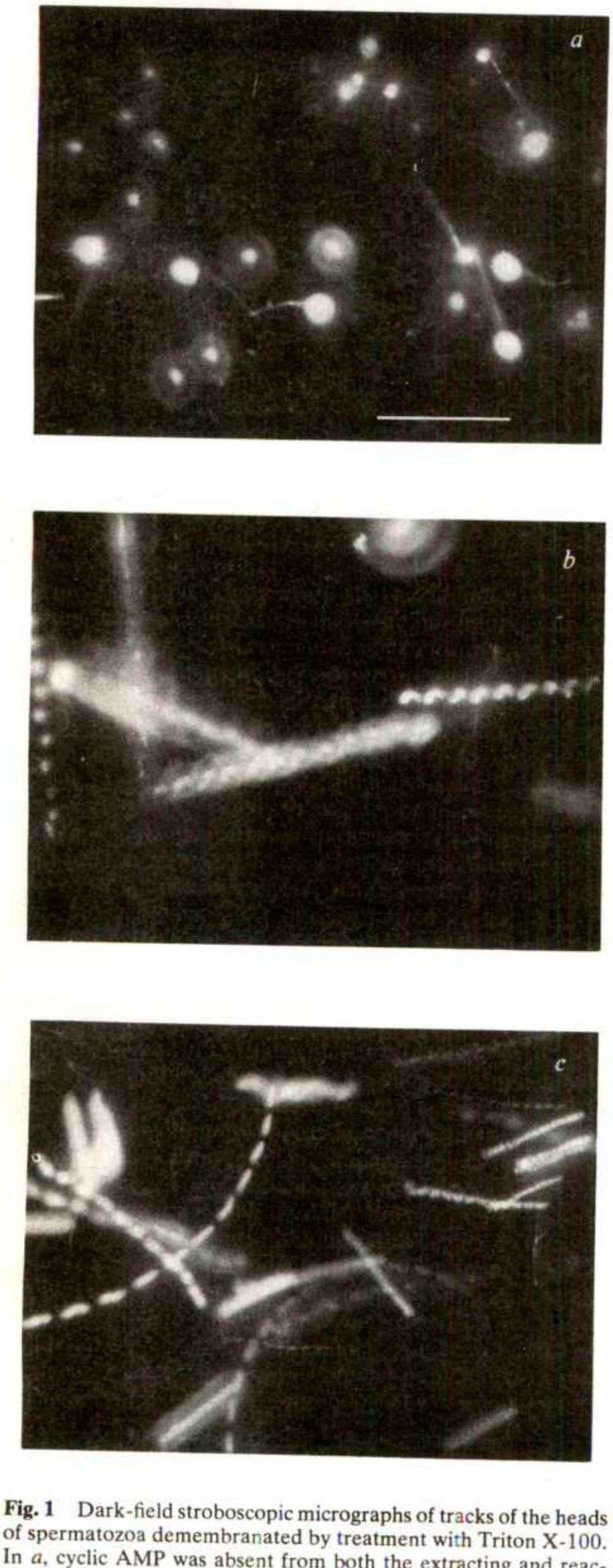

Fig. 1 Dark-field stroboscopic micrographs of tracks of the heads of spermatozoa demembranated by treatment with Triton X-100. In *a*, cyclic AMP was absent from both the extracting and reactivating media; semen was directly immersed in the extracting medium and demembranated; no evidence of movement. In *b*, cyclic AMP was present in the reactivating medium; demembranation of sperm was performed by the same method as in *a*; movement is evident. In *c*, cyclic AMP was absent from both the extracting and reactivating media; semen was diluted in 100 mM NaCl for 30 s and then spermatozoa were demembranated; movement is evident. In *a*, demembranated sperm are immotile; rounded heads and slender axoneme projected from heads are observed. In *b*, *c*, demembranated sperm are motile; the image of tracks of heads which are driven by axonemal movement are observed as a dotted line under stroboscopic illumination; all preparations exhibit straight or curved lines, no rounded heads are present, indicating 100% motility of axonemes. Bar in *a* indicates 50 μm.

placed in reactivating medium containing MgATP^{2-} but no additional cyclic AMP, axonemal movement occurred to give a speed of 78 ± 9 μm s^{-1} ($n = 4$). This can be explained if cyclic AMP becomes bound to the axoneme during the demembranated procedure, and induces its maturation. Axonemal movement can then occur with the addition of the energy source, MgATP^{2-} alone.

In the above experiments Ca^{2+} concentration was ~5 mM in the extracting medium and 10^{-9} M in the reactivating medium (buffered with EGTA). Even when CaCl$_2$ was eliminated from both media, axonemal movement occurred, suggesting that Ca^{2+} did not affect the maturation in motility of the axoneme.

During natural spawning, seminal K$^+$, which inhibits motility of salmonid sperm in the sperm duct, is diluted by fresh water, allowing sperm motility to occur[10]. In the present experiments, the mature axoneme deprived of plasma membrane and mitochondria always displayed motility in reactivating medium containing 0.15 M KCl, suggesting that K$^+$ ions inhibit the motility of intact (functionally mature) sperm through metabolic or membrane effects, and do not directly inhibit axonemal maturation. When an appropriate volume of semen was diluted to 100 vol in K$^+$-free 100 mM NaCl for 30 s (the duration of intact sperm motility of rainbow trout) and then a volume of the sperm suspension was extracted in the absence of cyclic AMP, axonemal movement occurred to give a speed of 100 ± 32 μm s^{-1} ($n = 11$) in reactivating medium containing MgATP^{2-}, again in the absence of cyclic AMP (Fig. 1*c*). This result offers an explanation for normal initiation of trout sperm motility: the reduction of external K$^+$ at spawning may affect metabolic or membrane-mediated processes in the intact sperm and thus induce an increase in intraflagellar cyclic AMP concentration. The endogenous cyclic AMP then induces axonemal maturation (as described above; Fig. 1*b*), and the matured axoneme conveys motility to the sperm, using energy provided by the mitochondria.

Components of the cyclic AMP system, including cyclic AMP, adenylate cyclase, phosphodiesterase, cyclic AMP-dependent protein kinase which phosphorylates the motile apparatus[11], and phosphoprotein phosphatase, occur in motile cells, including spermatozoa[12], cilia[11] and muscle[13], of many animals. The ability to isolate an immature motile apparatus from trout sperm provides a useful model for investigating cell motility, especially the molecular site of cyclic AMP action and phosphorylation in sperm motility and the chemistry of interaction between the cyclic AMP system and the motile apparatus in initiation of cell motility generally.

Independently of our present study, activation of demembranated spermatozoa of a tunicate *Ciona* by cyclic AMP has been described[14].

We thank H. A. Bern and C. J. Brokaw for critical evaluation of the manuscript, H. Mohri for encouragement, and the director and staff of Kumagaya Branch of Saitama Fisheries Experiment Station for providing the materials. This work was supported in part by a grant-in-aid from the Japanese Ministry of Education and Itō Foundation for the Advancement of Ichthyology to M. M.

Different mRNAs from the transforming region of highly oncogenic and non-oncogenic human adenoviruses

Anders Virtanen & Ulf Pettersson

Jean Michel Le Moullec, Pierre Tiollais & Michel Perricaudet

Unité de Recombinaison et Expression Génétique, Institut Pasteur, 28 rue du Dr Roux, 75724 Paris Cedex 15, France

Only a fraction of the genome of adenovirus, a DNA tumour virus, is required for transformation *in vitro*[1-4]. The leftmost 11% of the genome, including the two transcription units E1A and E1B, appear to be sufficient for transformation of rat embryo cells in tissue culture for highly, weakly and non-oncogenic adenovirus serotypes[5,6]. Various spliced mRNAs, orginating from the transforming region, have been identified[7-11] and in some cases the corresponding protein products found[12-14] but it is unknown what renders some serotypes highly oncogenic for baby hamsters compared with others that are non-oncogenic although able to transform cells *in vitro*. We have studied the mRNAs from the transforming region of the highly oncogenic serotype 12 (Ad12) in the hope of finding novel mRNAs which could account for the oncogenic properties of the virus. We have previously failed to find any differences between the spliced mRNAs in the transcription unit of the E1A region of Ad12 and the corresponding mRNAs from the non-oncogenic type 2 (Ad2)[15]. Here we have extended our analysis to the E1B region and show that the highly oncogenic Ad12 encodes mRNAs which have different structures from those encoded by Ad2.

We isolated mRNA from Ad12-infected cells and prepared cDNA copies which were inserted into the pBR322 vector. RNA was extracted[16] from infected A549 cells (a cell line derived from a human oat-cell carcinoma) either 8 h after infection in the presence of 25 μg ml^{-1} cycloheximide or 16 h post-infection in the absence of drug. To study the temporal expression of genes in the transforming region we prepared ^{32}P-labelled cDNA copies from the two mRNA preparations, and hybridized[17] these to restriction enzyme fragments of Ad12 DNA. The results (Fig. 1) show that the RNA from the cycloheximide-treated cells hybridized only to the *Acc*I H fragment which covers the E1A region of Ad12 (ref. 18). In contrast, RNA prepared 16 h post-infection in the absence of cycloheximide hybridized also to the *Acc*I F fragment and to two small fragments that are specific for region E1B (Fig. 1).

Double-stranded cDNA copies of late (16 h) poly(A)-containing RNA were prepared as described elsewhere[10] and inserted in the *Pst*I cleavage site of the pBR322 plasmid. Clones having sequences from the E1 region were identified by screening 50,000 colonies by hybridization[19] using ^{32}P-labelled *Eco*RI C fragment as probe. To distinguish between clones from regions E1A and E1B, the *Acc*I restriction fragments, 1, 2 and 3 (see Fig. 1) of the *Eco*RI C fragment were used and 38 E1B-specific clones were identified. Characterization of the clones by cleavage with endonucleases *Hin*dIII, *Sal*I, *Xba*I and *Pvu*II, which cleave the Ad12 DNA within region E1B (Fig. 2), showed that they correspond to three classes of spliced mRNA.

The structures of these classes were determined by sequencing parts of representative clones and comparing the results with

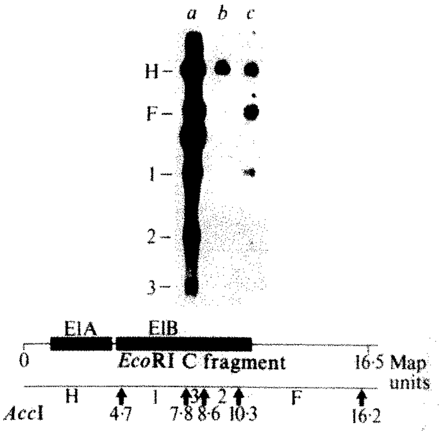

Fig. 1 Kinetic analysis of mRNA expression from the transforming region of Ad12. For this experiment we used a cloned *Eco*RI C fragment of Ad12 DNA comprising the leftmost 16% (M.P., unpublished data). *Acc*I cleavage of the cloned fragment results in five fragments of viral DNA which can be used to discriminate between regions E1A and E1B of Ad12. The lower panel shows a restriction enzyme cleavage map for endonuclease *Acc*I. Only the leftmost 16.5 map units are included and the fragments are indicated by numbers and letters. The top panel shows hybridization between *Acc*I fragments of Ad12 DNA and ^{32}P-labelled cDNA, prepared using AMV polymerase with oligo(dT) as primer. RNA extracted 8 h after infection (*b*) and 16 h after infection in the absence of drug (*c*) was tested. For the analysis a clone containing the *Eco*RI C fragment of Ad12 DNA (0–16.5 map units) was cleaved with *Acc*I and the resulting fragments separated on a 1.4% agarose gel before transfer to nitrocellulose[17]. ^{32}P-labelled Ad12 DNA was hybridized to a separate filter strip to visualize all fragments containing viral DNA (*a*). The band labelled H in the upper panel, contains the *Acc*I H fragment of Ad12 plus flanking sequences from the pBR322 plasmid.

the nucleotide sequence determined for the E1B region of Ad12 DNA (ref. 20 and K. Fujinaga *et al.*, personal communication). We thus established the way in which the three mRNA classes are spliced; mRNAs belonging to class I are spliced between nucleotides 3,295 and 3,369 and resemble closely the 22S mRNA from the E1B region of subgroup C adenoviruses[21]. RNA species belonging to class II have two introns; one is identical to the small intron in class I mRNAs, the second is large and located between nucleotides 2,046 and 3,163 in the sequence of Bos *et al.*[20]. Class III mRNAs also have two introns; one is large and identical to the large intron in class II mRNAs whereas the second is short and located between nucleotides 3,295 and 3,444. Thus the same donor site but different acceptor sites are used for splicing the small intervening sequences present in class II and III mRNAs. All 38 clones in our collection contained the *Xba*I cleavage site at map position 8.9, suggesting that no Ad12 mRNA has the same structure as the 13S mRNA of region E1B in Ad5 (ref. 21), which contains a single large intron.

S$_1$ nuclease analysis has identified a common poly(A) addition site both for the Ad12 E1B mRNAs[11], and the Ad5 E1B

Table 1 Characterization of 38 clones containing sequences from region E1B of Ad12

No. of clones	mRNA species*
4	I
8	II
4	III
22	Unclassified†

* As defined in Fig. 2.

† These clones contained severely truncated cDNA inserts and thus could not be classified unambiguously; most belong to class II and II mRNAs.

0028-0836/82/080705—03$01.00

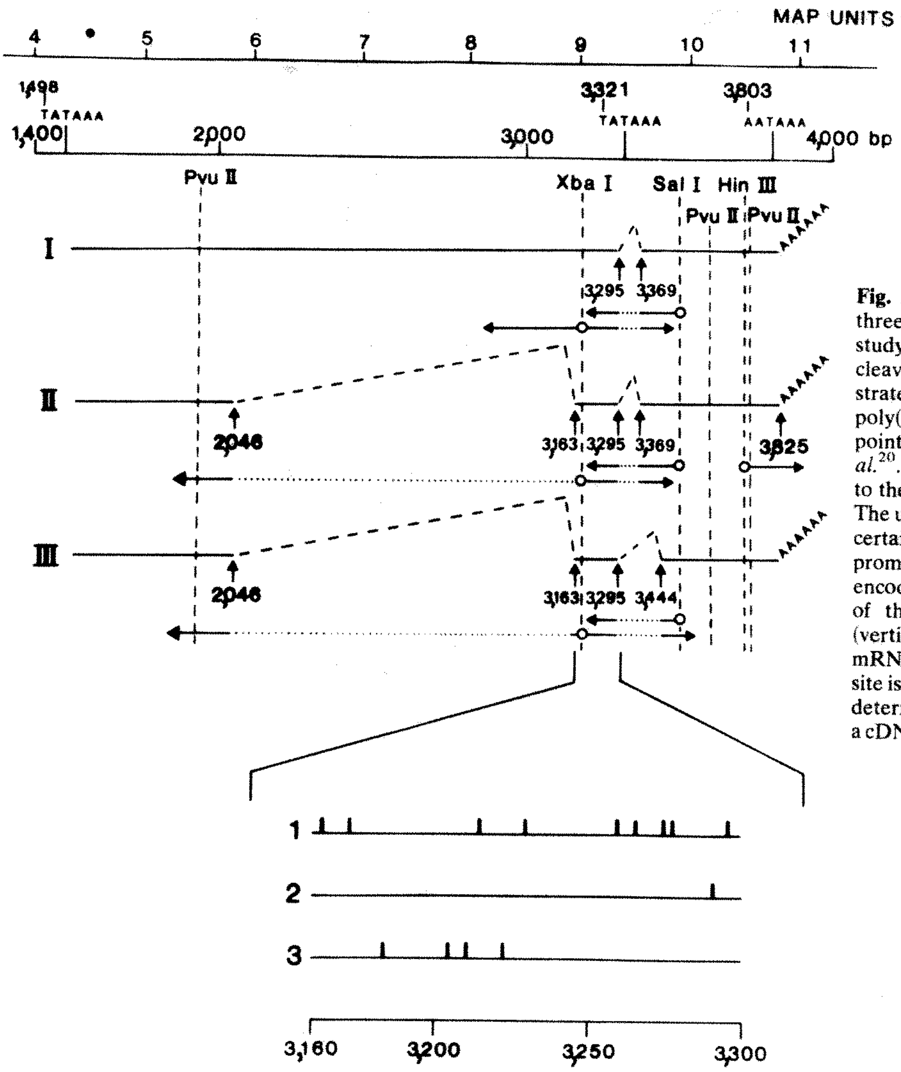

Fig. 2 Schematic drawing of the structure of the three classes of mRNA identified in the present study. The positions of selected restriction enzyme cleavage sites are indicated and the arrows demonstrate how the sequence was determined[28] at the poly(A) addition site and at the different splice points. The sequence is indexed according to Bos *et al.*[20]. The numbers at the exon/intron junctions refer to the first or last nucleotide of the respective exon. The upper part of the figure indicates the positions of certain sequences: TATAAA at position 3,321 is a promoter-like sequence which preceds the sequence encoding the Ad12 polypeptide IX. The lower part of the figure illustrates the termination codons (vertical bars) in the second exon of class II and III mRNAs (data from ref. 20). The poly(A) addition site is located immediately to the left of the sequence determined by Bos *et al.*[20] and was determined from a cDNA clone. Nucleotide 3,825 is the first A residue in the poly(A) tail. bp, Base pairs.

mRNAs[7,8]. By sequencing the ends of a cDNA insert (Fig. 2), the poly(A) addition site in region E1B of Ad12 was located at nucleotide 3,824. It is preceded by the hexanucleotide sequence AAUAAA, which is almost invariably adjacent to poly(A) addition sites in eukaryotic mRNAs[22].

The 5′ ends of the mRNAs belonging to the three classes cannot be determined from the present study. However, results of S_1 nuclease analysis suggest that all mRNAs from region E1B of Ad12 have a common 5′ end located around nucleotide 1,525 in the Ad12 sequence[11]. There are extensive sequence homologies between this region in Ad12 and the known E1B cap site in the Ad5 genome; furthermore, the sequence TATAAA (the 'Goldberg-Hogness box') lies between nucleotides 1,498 and 1,503.

The coding potential of the three classes of Ad12 mRNA can be predicted if it is assumed that they have common 5′ ends around nucleotide 1,525. Bos *et al.*[12] have shown that the E1B region of Ad12 has three major open translational reading frames. One very long reading frame starts with an ATG triplet at position 1,846 and ends with a UGA termination codon at position 3,292 (Fig. 3). This open reading frame has a theoretical coding capacity of molecular weight 54,000 (54 K) and could be used in its entirety only in the long mRNA (class I) with a single splice. When translated from this mRNA the protein would terminate immediately before the splice. The second long open translational reading frame starts with an ATG triplet at position 1,541 and ends at position 2,030 (Fig. 3). From the deduced mRNA structures it is apparent that the latter reading frame can theoretically be used in mRNAs belonging to all three classes (Fig. 3). Class I mRNAs are consequently polycistronic with two uninterrupted reading frames, possibly encoding two completely different polypeptide chains as has been proposed previously[20]. These would have molecular weights of 54 K, and 19 K, which roughly correspond to the molecular weights of two

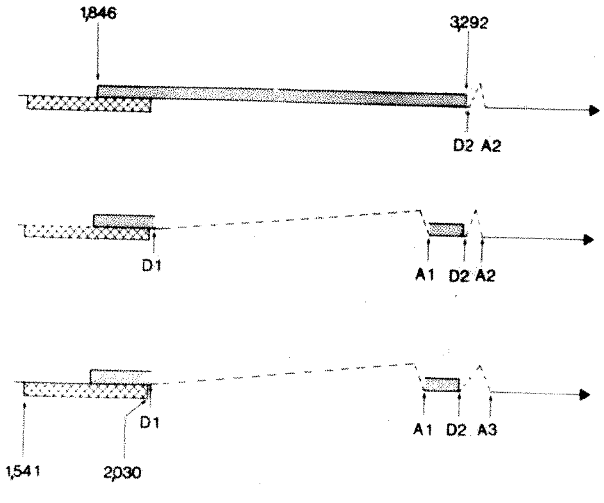

Fig. 3 The two major open translational reading frames in Ad12 as defined by Bos *et al.*[20] and their relationship to the structures of the Ad12 E1B mRNAs. The different acceptor (A) and donor (D) sites used to splice E1B mRNAs are indicated.

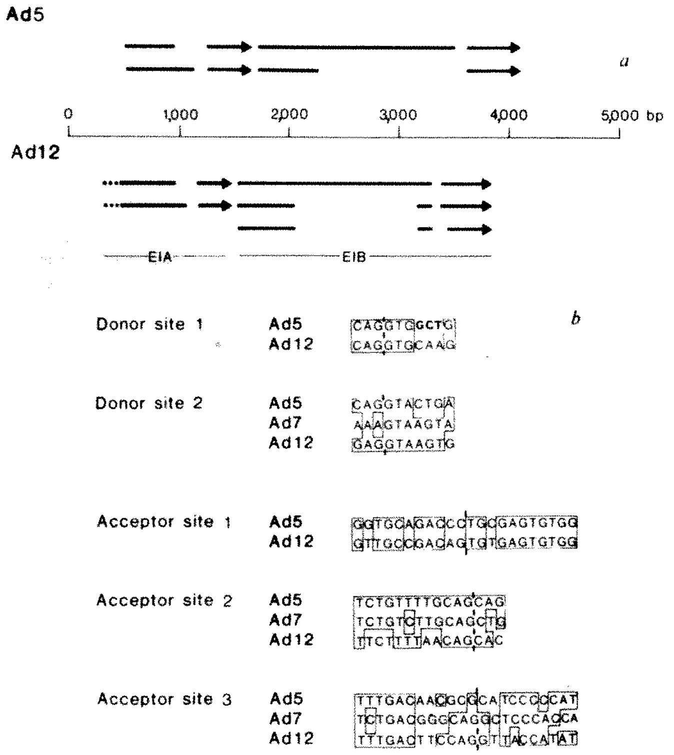

Fig. 4 Comparison of the transforming regions of highly oncogenic and non-oncogenic adenoviruses. *a*, Comparison of the major spliced mRNAs, transcribed from the transforming region of Ad5 and Ad12. *b*, Comparison of nucleotide sequences at different splice junctions in Ad5, Ad7 and Ad12. The donor sites D1 and D2, and the acceptor sites A1, A2 and A3, are defined in Fig. 3. Data for Ad12, Ad5 and Ad7 are from ref. 20, refs 29 and 30, and ref. 26 respectively.

polypeptides identified by translation *in vitro*[23]. If translation were initiated at the ATG triplet which precedes the long open reading frame (at position 1,846) in class II and III mRNAs, a polypeptide would be translated from sequences on both sides of the large splice present in these mRNAs (Fig. 3). The product would be a 12 K polypeptide, related to the 54 K polypeptide but lacking 372 internal amino acids. The third open reading frame in region E1B corresponds to polypeptide IX which is translated from an unspliced mRNA[20].

The existence of two alternative small introns in class II and III mRNAs is puzzling. Table 1 shows that both types are frequent and hence not the result of occasional incorrect splicing events. As the small exon in class II and III mRNAs contains stop codons in all three possible reading frames (Fig. 2), the coding capacity of class II and III mRNAs is the same.

Figure 4*a* outlines the mRNAs encoded by the transforming regions of Ad5 and Ad12. The most striking descrepancy between the highly oncogenic Ad12 and the non-oncogenic Ad5 is the existence in the former of two RNA species from region E1B which have a large and a small intron. No equivalent mRNA species have yet been reported from region E1B of subgroup C adenoviruses. The two alternative splices in class II and III mRNAs of Ad12 are both located in the 3′-noncoding part of the mRNA, which is very unusual. Introns in the 3′-noncoding region of cellular mRNAs have been rarely encountered previously[24], the only known example besides the E1B mRNAs being the splice present in the mRNA for the small T antigen of simian virus 40 (ref. 25). There are two ways in which the two small splices could influence the properties of class I and II mRNAs: either the structure of the 3′-noncoding region predetermines by some unknown mechanism which of the two possible initiation codons is chosen, thereby generating completely different polypeptides from class II and III mRNAs, or the different 3′-noncoding regions in class II and III mRNAs alter the stability or rate of transport of the mRNAs. Provided that the difference between oncogenic and non-oncogenic viruses is quantitative rather than qualitative, the unique 3′-noncoding parts of the Ad12 mRNAs could have a decisive role in determining the oncogenic potential of the virus. It should be possible to eliminate specifically the splice which generates the class III mRNAs by site-specific mutagenesis and thus test directly the hypothesis.

The results, summarized in Fig. 4 together with corresponding data from subgroup B and C adenoviruses, make it possible to compare directly nucleotide sequences at the positions where splicing occurs in region E1B of different adenoviruses. Two donor sites, D1 and D2, and three acceptor sites, A1, A2 and A3, for splicing can be identified in the three classes of Ad12 E1B mRNA (see Fig. 3). Figure 4*b* compares the sequences at the donor and acceptor sites in region E1B of Ad12 with the corresponding sequences in Ad5 and Ad7. The results show that the donor site D1 is well conserved and apparently used to generate a large splice in both Ad5 and Ad12. In addition the second donor site, D2, is well conserved and apparently used to generate a small splice in Ad5, Ad7 (ref. 26) and Ad12. This is in contrast to the leftmost acceptor site A1 which in Ad12 generates the middle splice, not found in Ad5 mRNAs. Sequence homology is observed around the splice site but the A-G dinucleotide is altered in Ad5, which presumably makes it non-functional[27]. The acceptor site A2 is, as expected, conserved in all three serotypes in contrast to the third acceptor site A3 which is unique for serotypes 7 and 12. Although there is no direct evidence, we can predict from sequence similarities that the E1B mRNAs of Ad7 resemble those of Ad12. The similarity between Ad7 and Ad12 with regard to acceptor and donor sites in region E1B supports the idea that, as was recently proposed[15], the highly and weakly oncogenic adenoviruses have evolved together.

We thank Elsy Johnsen for technical assistance and Marianne Gustafson for secretarial help. The gift of reverse transcriptase from Dr J. Beard is also acknowledged. This investigation was supported by grants from the Swedish MRC, the Swedish Cancer Society, CNRS, INSERM, and Fondatione pour la Recherche Medicale.

Site-specific mutagenesis by error-directed DNA synthesis

Richard A. Zakour & Lawrence A. Loeb*

The Joseph Gottstein Memorial Cancer Research Laboratory,
University of Washington, Department of Pathology SM-30, Seattle,
Washington 98195, USA

An important experimental strategy for defining functional regions of a DNA sequence involves deleting or mutating particular sequences *in vitro* and observing the effects of the changes in a functional assay. We have approached the problem of making specific changes at defined sites in a nucleotide sequence by attempting to make use of the mistakes made by DNA polymerase enzymes while copying a sequence. Our approach is to initiate DNA synthesis from an isolated restriction fragment, and to elongate the fragment to a designated position by sequentially adding complementary nucleotides, then to incorporate the non-complementary nucleotide using an error-prone DNA polymerase followed by continuation of faithful synthesis. Here we demonstrate by DNA sequence analysis that both transitions and transversions can be produced at a designated position on the DNA template using this method.

DNA polymerases from prokaryotes contain a proofreading $3'\rightarrow5'$ exonuclease activity that enhances their accuracy in catalysis[1]. This associated exonuclease excises any non-complementary nucleotides at a primer terminus before continuing polymerization. In contrast, DNA polymerases from RNA tumour viruses and eukaryotes incorporate non-complementary nucleotides at higher frequency during copying of synthetic polynucleotides[2] and natural DNA[3]. The non-complementary nucleotides incorporated are invariably found to be present as single-base substitutions. Because the frequency of misincorporation by DNA polymerases is proportional to the ratio of non-complementary to complementary nucleotides in the reaction mixture, it should be possible to force a particular non-complementary nucleotide to be incorporated by carrying out the reaction in the presence of only that deoxynucleoside triphosphate. Incorporation of a series of non-complementary nucleotides is unlikely, as it would result in separation of the primer terminus from the template and diminish further synthesis.

To study the feasibility of using nucleotide misincorporation during *in vitro* DNA synthesis for site-specific mutagenesis, we chose to copy single-stranded bacteriophage ΦX174 circular DNA template containing an amber mutation. The frequency of mutagenesis can be determined from the reversion frequency of the copied DNA in transfection assays and the specificity of mutagenesis can be documented by sequence analysis[4,5].

Restriction endonuclease cleavage fragment, *Hpa*I 2 (ΦX174 positions 31–1,294)[6] from ΦX174 RF DNA, was hybridized to ΦX174 amber (*am*)18 template DNA. The 3′ OH terminus of this restriction fragment is located seven nucleotides from the change that causes the amber 18 mutation (*am*18 contains a T in place of C at ΦX174 position 23)[7]. We first elongated the 3′ OH terminus of the restriction fragment primer using *Escherichia coli* DNA polymerase I (Pol I) with only dATP and dCTP. These nucleotides are complementary to the first three template positions beyond the 3′ OH primer terminus (Fig. 1). After isolating template containing the elongated primer, a second series of reactions was carried out using avian myeloblastosis virus (AMV) DNA polymerase. Three different combinations of deoxynucleoside triphosphates were used (Fig. 1). After incubation of the reaction mixtures for 5 min at 37 °C in the presence of the specified nucleotides, all four deoxynucleoside triphosphates were added. Synthesis was allowed to proceed for an additional 5 min, so that any misincorporated nucleotides on termini would be protected from excision by the subsequent incorporation of the next complementary nucleotide. EDTA was added to stop synthesis, and the copied DNA was transfected into *E. coli* spheroplasts. Synthesis was completed by the *E. coli* replicating complex *in vivo*. We determined the reversion frequency of the *am*18 mutation by measuring the number of infective centres[4,8,9].

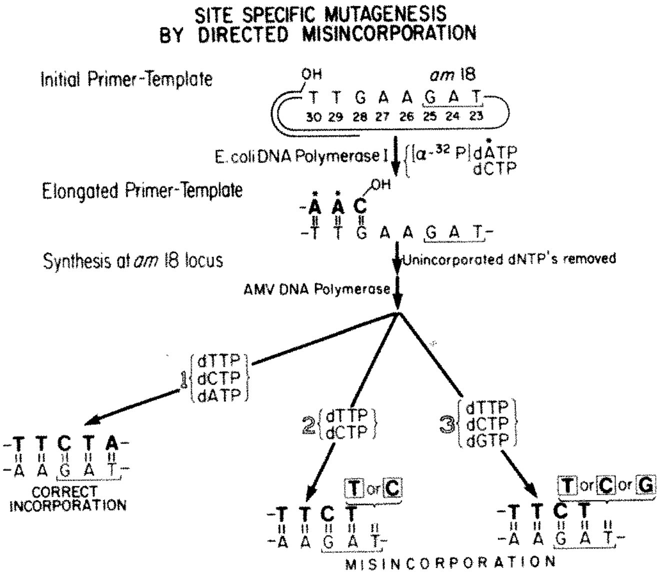

Fig. 1 Steps involved in primer elongation and site-specific mutagenesis. Primer elongation with complementary nucleotides: *Hpa*I 2 restriction endonuclease fragment was hybridized to single-stranded ΦX174 *am*18 DNA. Limited elongation of the 3′ OH terminus of the primer was carried out with Pol I. The reaction contained 3 μg of primed template, 5 μg of Pol I, 1 μM [α-^{32}P]dATP, 1 μM dCTP, 5 mM $MgCl_2$, 2 mM dithiothreitol and 20 mM Tris-HCl (*p*H 8.0) in a volume of 100 μl. Incubation was at 37 °C for 5 min. The reaction was stopped by adding EDTA to a final concentration of 10 mM; the mixtures were heated to 65 °C for 10 min and extracted once with an equal volume of redistilled phenol equilibrated with 20 mM Tris-HCl (*p*H 8.1) containing 1 mM EDTA and 100 mM NaCl. To separate the DNA from the unincorporated nucleotides, the aqueous phase was loaded onto a Sephadex G-100 column (1 × 60 cm) and the column eluted with 0.15 mM KCl, 50 mM Tris-HCl (*p*H 7.8). Fractions (1 ml) were collected and aliquots (20 μl) processed for determination of acid-insoluble radioactivity. The peak fractions were pooled, 1/10th volume of 3 M sodium acetate was added, and the DNA was precipitated with EtOH. The DNA was pelleted, washed and resuspended in 100 μl of 10 mM Tris-HCl (*p*H 8.0) containing 0.1 mM EDTA. Synthesis at *am*18 locus: A second series of *in vitro* DNA reaction mixtures each contained 0.1 μg *am*18 ΦX174 DNA primed with the elongated *Hpa*I 2 restriction fragment, 1 U of AMV DNA polymerase, 50 mM Tris-HCl (*p*H 8.0), 5 mM $MgCl_2$ and 2 mM dithiothreitol in a volume of 50 μl; they were incubated at 37 °C for 5 min. All reaction mixtures contained 10 μM dTTP and dCTP to elongate the primer correctly to position 23 of the *am*18 locus. Various combinations of the other deoxynucleoside triphosphates, each at a concentration of 10 μM, were included in individual reactions as indicated. (1) Correct incorporation is achieved by including the three nucleotides complementary to the *am*18 locus, dTTP, dCTP and dATP. (2) The presence of only dTTP and dCTP during directed misincorporation synthesis will allow the misinsertion of either T or C at position 23 of the *am*18 locus. (3) By including dTTP, dCTP and dGTP during directed misincorporation synthesis, it should be possible to obtain T, C, or G misinsertion at position 23. In experiments performed in this manner, G substitution at position 23 was the only change observed among seven revertants (Table 2). Synthesis with AMV DNA polymerase was followed by *in vitro* DNA synthesis with all four deoxynucleoside triphosphates present to seal the misincorporated nucleotide into the newly replicated DNA. Reactions were stopped by adding 0.1 vol of 100 μM EDTA.

When dATP, the nucleotide complementary to position 23 in the *am*18 region, was present in addition to dCTP and dTTP during DNA synthesis using AMV DNA polymerase, the reversion frequency of the newly synthesized DNA product in the transfection assay was fourfold higher than that of the

uncopied primed template (Table 1, lines 1, 2). This increase, which is a function of the error-prone nature of AMV DNA polymerase[2], provides the background reversion frequency (4×10^{-4}). In both the nucleotide substrate combinations studied (Table 1, lines 3, 4), in which dATP was excluded from the reaction, the reversion frequencies were increased 100-fold. These higher reversion frequencies were presumably due to the substitution by AMV DNA polymerase during the *in vitro* synthesis of one of the non-complementary nucleotides for the missing complementary dATP.

To determine more precisely the efficiency of non-complementary nucleotide misinsertion, we measured the reversion frequency of a population that included only copied DNA molecules. Following mutagenesis with AMV DNA polymerase, synthesis was allowed to continue completely around the ΦX174 template using all four deoxynucleoside triphosphates, and a double-stranded closed circular molecule was formed using DNA ligase; nuclease S_1 was then used to hydrolyse the single-stranded molecules. In initial experiments, the reversion frequency of molecules copied past the *am*18 locus with dCTP, dGTP and dTTP (Table 1, line 4) was increased to 33%. Thus, enrichment for copied DNA molecules should provide designated mutants, even in the absence of a biological procedure for mutant selection.

To show that the increased reversion frequencies were a result of single-base substitutions, we sequenced the DNA of individual revertants. The nucleotide in position 23 of the minus strand was confirmed to be G in wild-type DNA and A in *am*18 DNA (Table 2, line I). In six spontaneous revertants, G substituted for A at position 23. Among the eight revertant DNAs, from reactions in which only dCTP and dTTP were present, seven contained cytosine and one contained thymidine at position 23 (Table 2, line II-1). These changes were probably a result of T-C and T-T mispairings during *in vitro* DNA synthesis. When dGTP was included in the synthesis reaction with dCTP and dTTP, all seven of the revertant DNAs contained G at position 23 (Table 2, line II-2), indicating a T-G mispairing. Thus, all three misincorporations occurred opposite this template thymidine during the *in vitro* DNA synthesis. The substitutions at ΦX174 position 23 were the only changes that we observed in the DNA sequence analysis. This observation suggests that the reaction conditions yielded misinsertions predominantly at the predetermined template position, the first template position the polymerase encountered that lacked a complementary nucleotide.

The patterns of nucleotide misinsertion observed in these experiments indicate that AMV DNA polymerase is capable of catalysing pyrimidine–pyrimidine as well as purine–pyrimidine mispairings. Based on the revertant DNAs that we screened, when dATP was the only nucleotide deleted during synthesis, the presence of dGTP resulted in only T→C transitions, produced by T-G mispairing during synthesis. Despite the presence of both dCTP and dTTP, we observed no transversions in DNAs derived from these copying conditions, even though we have observed that substitutions of these nucleotides at position 23 are genetically viable. Thus, it seems that T-G mispairing may be more likely to occur than either T-T or T-C mispairing. This observation agrees with investigations by others in suggesting that purine–pyrimidine mispairing should be favoured over pyrimidine–pyrimidine mispairing[10,11].

Table 2 DNA sequence analysis of revertants obtained from copying *am*18 DNA with AMV DNA polymerase in the presence of defined deoxynucleoside triphosphate substrates

	Sequence at position [minus (copied) strand] 25	24	23	No. of DNAs sequenced
I. Controls				
1. Wild type	C	T	G	2
2. *am*18	C	T	A	2
3. Spontaneous revertants	C	T	G	6
II. Revertants, added dNTPs				
1. dTTP, dCTP	C	T	C	7
	C	T	T	1
2. dTTP, dCTP, dGTP	C	T	G	7
	C	T	C	0
	C	T	T	0

Viral template DNA which was wild type for *am*18 was isolated from *am*3 ΦX174 bacteriophage (a gift of J. Weiner and A. Kornberg) and DNA from *am*18 was isolated from ΦX174 *am*18 bacteriophage (a gift of P. Weisbeek) as previously described[4,8]. Spontaneous *am*18 revertants were derived from non-permissive infective centres obtained from transfection of uncopied *am*18 molecules. Revertant DNAs were isolated from plaque-purified non-permissive infective centres obtained from *am*18 DNAs copied with AMV DNA polymerase as described in Table 1 legend. Isolation of revertant phage and preparation of viral template DNA for sequencing were performed as described elsewhere[5]. The DNA sequence from ΦX174 positions 1–26 of wild type, *am*18 and revertants of *am*18 were determined by the chain terminator method of Sanger *et al.*[23]. A preparation containing all three fragments from a *Hpa*I restriction digest of ΦX174 RF DNA was used to prime each single-stranded template at a ratio of 1 : 1. The sequencing reactions contained *E. coli* DNA polymerase I at an enzyme to template ratio of 10 : 1 and dideoxy- to deoxynucleotides at a ratio of 200 : 1. After completing the polymerization reactions, restriction endonuclease *Taq*I was added at a ratio of 1 unit per µg of DNA and the sample was incubated at 65 °C for 60 min. The products of the sequencing reaction were displayed on a 12% polyacrylamide gel. The DNA sequence in the *am*18 region (ΦX174 position 23–25) can be unambiguously read because all synthesis initiated at the other *Hpa*I restriction fragment primers are in larger *Taq*I digestion fragments that do not migrate into the readable portion of the gel.

Table 1 Reversion frequency of *am*18 DNA copied by AMV DNA polymerase in the presence of various combinations of deoxynucleoside triphosphate substrates

Added dNTPs	Non-permissive infective centres ($\times 10^1$) (revertants)	Total infective centres ($\times 10^5$)	Reversion frequency ($\times 10^{-4}$)
1. None	3.5	3.41	1
2. dTTP, dCTP, dATP	3.5	0.79	4
3. dTTP, dCTP	291	0.76	383
4. dTTP, dCTP, dGTP	182	0.45	404

The *am*18 template DNA with an elongated *Hpa*I2 primer was copied with AMV DNA polymerase as described in Fig. 1 legend in the presence of the indicated deoxynucleoside triphosphates. The transfection procedure for determining the number of infective centres and the reversion frequency has been described previously[4,8].

From these experiments, we propose that a general method for site-specific mutagenesis can be developed using directed misincorporation during DNA polymerization. The most direct application is with single-stranded or gapped DNA templates. Site-specific mutagenesis of double-stranded DNA can also be performed by this method when cloned into a bacteriophage M13 single-stranded vector. The first step of the procedure is to elongate a primer terminus to reach a pre-selected site by using a prokaryotic. DNA polymerase and different nucleotide combinations. This can be done in a series of reactions to achieve any required degree of elongation[12]. Pol I is particularly suitable for the elongation steps because it is highly accurate with natural DNA templates, the error rate being about 1 in 10^6 (ref. 5). For incorporation of a single non-complementary nucleotide, AMV DNA polymerase offers several advantages. First, it lacks a 3′→5′ exonuclease activity and is thus unable to excise a non-complementary nucleotide once incorporated[13]. Second, because AMV DNA polymerase can add complementary nucleotides into terminal single-base mismatches, misinsertions are sealed in place by subsequent correct nucleotide incorporations. Most importantly, in the presence of all complementary nucleotides, the frequency of misincorporation by AMV DNA polymerase is much higher than by polymerases containing proofreading activities[2,9]. Thus, in copying a natural DNA template, AMV DNA polymerase can be forced to be even more error prone by omitting any complementary nucleotide substrate (that is, an 'infinite pool bias') from the *in vitro* synthesis reaction. An alternative approach is to use Pol I in the presence of only a designated non-complementary deoxynucleoside thiotriphosphate. This analogue is incorporated with normal base-pairing properties but not excised by the 3′→5′ activity of the polymerase[14].

Site-specific mutagenesis at a predetermined position on a DNA molecule has become more feasible with the accumulation of DNA sequence information from a variety of genes. To date, three methods have been used to introduce specific base mutations into DNA. The first requires the chemical or enzymatic synthesis of an oligonucleotide that contains a designated single-base change[15–17]. The oligonucleotide is hybridized onto a template and extended into a biologically active molecule by *in vitro* DNA synthesis. Even though this may be the most exacting method of site-specific mutagenesis, each different substitution requires a unique oligonucleotide of sufficient length to form a stable hybrid with a specific region of the template[15,16,18]. In the second approach, nucleotides in a DNA template are modified to promote mispairing during *in vitro* gap repair synthesis. For example, sodium bisulphite has been used to deaminate specific template cytosines which thereafter will pair with adenine instead of guanine during DNA synthesis to produce C:G→T:A transitions[19,20]. With the third method, base substitutions are produced by misincorporation of a nucleotide analogue in place of a complementary nucleotide during *in vitro* nick translation. For example, by substituting N^4-hydroxy-dCTP for dTTP, A:T→G:C transitions were produced[21,22]. These latter two approaches are restricted to a single type of base substitution. Moreover, it is difficult to introduce the substitution only at a single designated site.

In addition to incorporating a non-complementary nucleotide at a particular site, the method outlined here can be used to generate a 'library' of mutations at a particular region. A restriction endonuclease fragment can be sequentially elongated to produce a new set of fragments of increasing length that can be isolated from a polyacrylamide gel. Each elongated restriction endonuclease fragment can then be used as primer for incorporating a non-complementary nucleotide. A set of elongated fragments isolated from a single gel could be used to produce a series of substitutions throughout a specific region of a gene.

We thank Drs T. A. Kunkel, R. Monnat and R. M. Schaaper for useful discussions and E. James for technical assistance. The procedure for isolating only copied ΦX174 DNA molecules was provided by T. A. Kunkel before publication. This investigation was supported by NIH grants CA-24845 and CA-24998 and NSF grant PCM 76-80439. R.A.Z. is a postdoctoral fellow of the National Institute of General Medical Sciences (GM-07115).

No evidence for 'stress' α-globin genes in chicken

Phenylhydrazine-induced anaemia in goats and certain sheep carrying a β^A-globin gene, leads to a switch from adult β^A-globin mRNA to β^C mRNA synthesis[1]. The β^C globin chains are also transiently produced late in fetal life. The nucleotide sequence of selected fragments of cloned goat β^C globin gene[2] corresponds to the amino acid sequence determined some years ago[3]. A similar reactivation of globin genes has been reported for the baboon, *Papio cynocephelus*, where anaemic stress also leads to the production of fetal haemoglobin[4]. In the case of anaemic chicken, results of cDNA cloning and nucleotide sequencing experiments suggested that a novel type of α-globin gene, the 'stress' gene, is expressed[5]. The existence of such a gene was mainly supported by the fact that the cDNA nucleotide sequence did not agree with any known chicken α-globin chain amino acid sequence. In contrast, we now report results, including a reinvestigation of the α^A-globin amino acid sequence, which reveal that in the anaemic chicken, the α^A gene is expressed, and there is no evidence for a specific stress α-globin gene.

Reactivation of genes due to physiological stress, such as induction of anaemia, is an important concept in the regulation of gene activity. The difference between the stress gene reported in chicken and the fetal genes of animals mentioned above is that the protein product of the stress gene could not be identified among the adult (α^A, α^D and β) or embryonic (π, π′, α^A, α^D, ε and ρ) globin chains[6]. Therefore, this switch seems not to represent a reactivation of a fetal-type gene. For further analysis of globin-coding sequences expressed in anaemic chicken, globin mRNA was isolated from polychromatic erythrocytes, transcribed into cDNA and cloned in bacterial plasmids[7]. Hybrid arrested cell-free translation from nine randomly selected clones demonstrated that six clones contain sequences coding for α chains and three sequences coding for β chains. The integrated sequence of one of the plasmids containing an α-globin sequence (pα^A HG3), which is 581 nucleotides long, was cleaved by *Pst*I, and after digestion with different restriction enzymes (see Fig. 1) the various fragments were submitted to

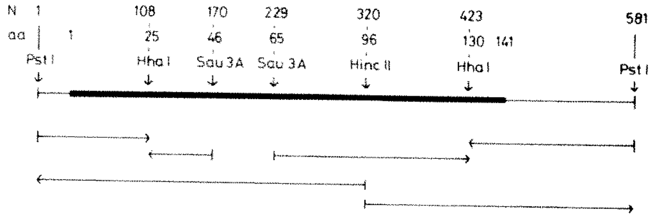

Fig. 1 Restriction map and sequencing strategy of the cloned nucleotide sequence cleared by *Pst*I from plasmid pα^A HG3. N refers to the number of nucleotides and aa to the number of amino acids, after which cleavage by restriction endonucleases occurs. The ends of the cloned sequence are tailed by ~20 G-C base pairs, originating from the G-C insertion technique in plasmid pBR322[7]. Restriction fragments, as shown by arrows, were subjected to sequence analysis (see Fig. 3).

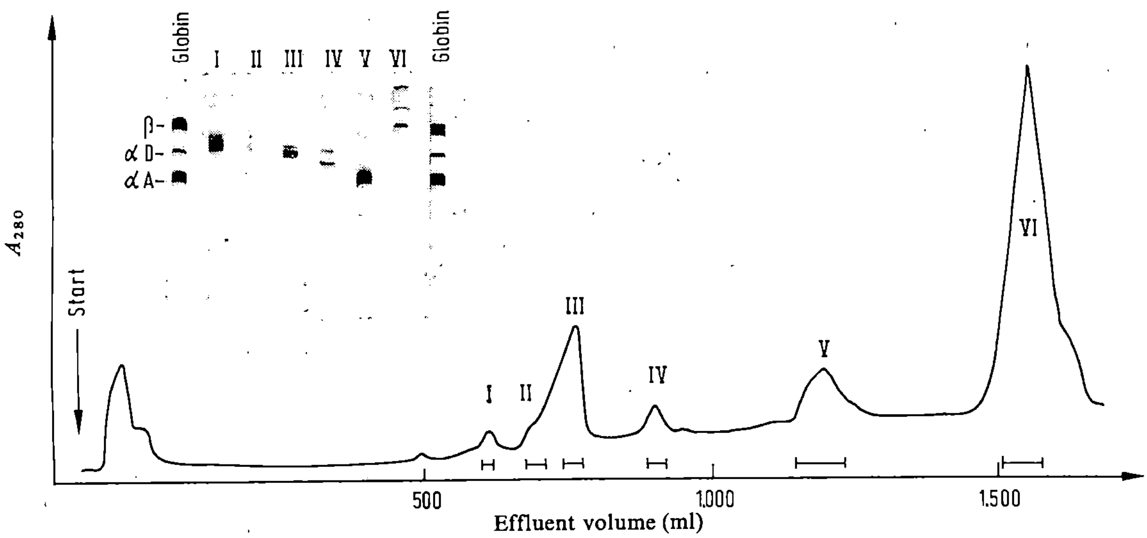

Fig. 2 Carboxymethyl-cellulose chromatography and Triton X-100 electrophoresis of chicken globin chains. Globin chains were isolated from erythrocyte lysates by precipitation of the 100,000*g* supernatant with acidic acetone and submitted to CM-cellulose (CM 52, Whatman) chromatography[15]. The eluting material was further analysed by Triton X-100 polyacrylamide gel electrophoresis[16] (inset).

nucleotide sequence analysis. The resulting nucleotide sequence includes the entire protein-coding region (see Fig. 3) and is very similar to sequences previously reported independently by three other groups[8–10]. The amino acid sequence derived from our cloned structural α-globin gene is identical with that of one of these three groups[9], although there are variations in the third bases of six codons. Our sequence differs at amino acid positions 110 and 121 or at positions 92, 93, 94 and 120, respectively, from the sequences published by the other two groups[8,10]. Although the origin of these differences is not known, it is concluded that our cloned sequence, as well as those reported by the above groups[8–10], represent the processed transcripts of the same gene coding for the major α-globin chain component of polychromatic erythrocytes in anaemic chicken.

A comparison of the amino acid sequence derived from our nucleotide sequence showed differences from embryonic π or π′ chains[11] at 60 positions, from the adult α^D chain[12] at 61 positions and from the adult α^A chain[13] at 22 positions. Thus it seemed that the cloned globin-coding sequence from anaemic chicken differs from the structural genes coding for these α-type chains. However, we re-examined the data for the α^A chain because (1) amino acid composition data[6,14] correspond better to our nucleotide-derived sequence than to the published sequence[13], and (2) a comparison of this α^A chain with the amino acid sequence of the major α-chain component of phylogenetically related animals, such as pheasant (see Fig. 3), revealed a rather large number of 21 exchanges.

For this reinvestigation, the native globin of adult chicken was separated by CM-cellulose (CM 52) chromatography[15], and the different peaks were further analysed by Triton X-100 polyacrylamide gel electrophoresis[16] (Fig. 2). Peak V was identified as the major α component, α^A. The relatively small absorbance can be explained by the fact that the α^A chains contain no tryptophan in contrast to four in the β chains[17] and one in the α^D chains[12]. The CM elution profiles and the electrophoretic patterns of globin chains from mature and immature cells were identical (data not shown). Amino acid analysis was performed on complete chains, tryptic peptides and the C-terminal fragment generated by acidic hydrolysis of the Asp–Pro peptide bond[18] using a Beckman model 121 C amino acid analyser. The chains and peptides were degraded automatically in a Beckman 890 B sequenator or in a Beckman 890 C sequenator with programs as reported elsewhere[15]. The phenylthiohydantoin derivatives of the amino acids were identified by TLC and HPLC[19].

There were no differences in the peptide patterns, amino acid analysis of chains and peptides as well in the sequences of few peptides that reportedly differ in α^A and stress gene products, regardless of whether α chains were isolated from mature or immature blood cells. Figure 3 shows the sequence, which corresponds to that derived from the nucleotides. Moreover, it is obviously homologous to the major α-chain component of the closely related species pheasant (only five differences at positions α28, α34, α38, α70 and α77), thus supporting the validity of our results. Our sequence data differ at 22 amino acid residues from that reported more than 10 years ago[13]. We are unable to identify such a chain in normal or anaemic chicken.

These findings demonstrate that the cloned sequence actually represents the structural gene sequence of the chicken α^A-globin chain. There is no reason to postulate a specific type of α-globin gene which is expressed during anaemic stress[5]. There was also no evidence of such a stress gene when the genomic arrangement of the complex α-globin gene family was investigated[20]. Moreover, a direct comparison of α chains from erythrocytes of uninduced animals and from polychromatic erythrocytes of anaemic animals (7 days after first phenylhydrazine injection) revealed no differences. Whether anaemia for longer periods induces reactivation of embryonic genes similar to that found in sheep and goats[1] cannot be excluded and remains to be elucidated. However, it is clear that the cloned α-globin cDNA

Fig. 3 *a*, Nucleotide sequence of the structural globin gene cloned in pα^A HG3 (see Fig. 1); *b*, amino acid (aa) sequence of chicken α^A-globin chain; *c*, amino acid sequence of the major α-chain component of pheasant.

sequence derived from globin mRNA of phenylhydrazine-induced anaemic chicken does not code for a novel type of globin chain but for the adult α^A-globin chain that is expressed in normal chicken.

Since submission of this work, others[21] have reported that they were unable to detect an anaemic shock α-globin gene by investigation of the genomic α-globin gene family in adult chicken.

We thank Professor H. Tiedemann for his continuous interest and generous support, and acknowledge the technical assistance of Miss E. Müller.

Univalent antibodies kill tumour cells *in vitro* and *in vivo*

M. J. Glennie* & G. T. Stevenson

Lymphoma Research Unit, Tenovus Laboratory, Southampton
General Hospital, Southampton SO9 4XY, UK

Antibody molecules are bivalent, or less often multivalent, with each antibody site within a single molecule having the same specificity. Bivalency must enhance the tenacity of antibody attachment to cell surfaces, as dissociation will require simultaneous release at both sites. However, the bivalency of the antibody sometimes induces a target cell to undergo antigenic modulation[1–3], thereby offering the cell a means of evading complement and the various effector cells recruited by the antibody. We have investigated the attack by univalent antibodies, which, despite removal of one antibody site, retain their Fc zones and hence their ability to recruit the killing agents, on neoplastic B lymphocytes of the guinea pig L_2C line. Rabbit antibodies raised against surface immunoglobulin of these cells were partially digested with papain to yield the univalent Fab/c derivatives[4,5]. We report here that these derivatives showed enhanced cell killing both *in vitro* and *in vivo*, and that this enhancement appeared to derive from avoiding antigenic modulation.

The L_2C lymphocytic leukaemia arose spontaneously around the year 1950 in a female guinea pig of the inbred strain 2, and has since been maintained by passaging *in vivo*; the line maintained in our laboratory was obtained in 1972 from Drs I. Green and E. Shevach (NIH). Blood from near-terminal animals was obtained by cardiac puncture and yielded L_2C preparations[6] of >95% viability with <2% contaminating leukocytes. The cells are lymphoblastic and exhibit surface immunoglobulin M (IgM), ~50,000 molecules per cell, of light chain class λ[7].

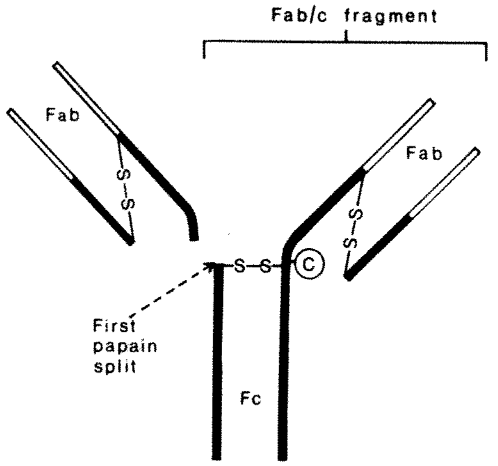

Fig. 1 Preparation of Fab/c from rabbit IgG antibody. The A12 allotypic variant of IgG[17], apparently more common than the allelic A11, possesses a threonine residue on each heavy chain immediately N-terminal to the hinge-region disulphide. An oligosaccharide unit © is attached to the threonine, but on one chain only, rendering this chain relatively resistant to enzymatic cleavage in the vicinity[18]. The chain lacking the oligosaccharide unit is cleaved as shown by brief exposure to papain, yielding the Fab/c fragment.

Here we used two IgG antibodies raised in rabbits to study attack on L_2C cells. Antibody reacting with constant determinants on the λ chain of L_2C surface immunoglobulin (anti-λ) was used for studies *in vitro*; the antibody was raised against serum $F(ab')_2$ $\gamma\lambda$ and prepared as pure IgG antibody by elution from λ chains coupled to immunosorbent[8]. Antibody specific for idiotypic determinants of the surface immunoglobulin (anti-Id) was used for studies *in vitro* and, because it is effectively tumour specific, for therapy *in vivo*[9]. It was raised against Fab μ isolated from the surface IgM[9], rendered specific for idiotypic determinants by absorption with guinea pig normal immunoglobulin, and used in the form of total IgG isolated from the absorbed antiserum.

The Fab/c derivatives of anti-λ and anti-Id, in which the antibody molecule is rendered univalent by removal of just one Fab arm[4,5] (Fig. 1), were prepared by digesting IgG antibody with thiol-free papain (0.8 mg ml^{-1}) at 37 °C for 4 h, *p*H 7.4. The products of digestion were fractionated by recycling chromatography on Ultrogel AcA44. To remove any contaminating $F(ab')_2$, the Fab/c was purified further by elution from an anti-Fc immunosorbent. In subsequent work we have used more limited exposure to papain (0.01 mg ml^{-1} at 37 °C for 30 min) in the presence of dithiothreitol (1 mM), and have been able to omit the immunosorptive step; after removing the thiol the hinge-region disulphide of Fab/c, possibly required for efficient activation of complement[10,11], can re-form by oxidation. Fab/c emerged from AcA44 columns in a zone corresponding to a molecular weight of ~100,000, and was obtained with a yield of 10–20% of the starting IgG. It was shown by precipitin analysis on Ouchterlony plates to possess both Fab and Fc determinants; and by gel chromatography of reduced material in 1 M propionic acid to comprise one light chain, one heavy chain and one-half of a heavy chain.

Previous work[3] has shown that both anti-λ and anti-Id induce rapid antigenic modulation *in vitro*: exposure of the L_2C cells to antibody at 37 °C for 2 min or longer confers resistance to lysis when they are subsequently exposed to antibody plus complement. In contrast to an earlier report describing the mouse TL system[12], bivalency of the antibody was found to be essential for induction of this modulation. It seems therefore that the redistribution of cell surface immunoglobulin induced when it is tethered by bivalent antibody—leading to patching, capping and endocytosis of the antigen–antibody complexes[13]—underlies the modulation of this antigen, although the extent of redistribution required is not clear.

Fab/c derivatives of both anti-λ and anti-Id were shown by indirect immunofluorescence to bind to the surfaces of L_2C cells. However, in contrast to the parent antibodies, there was no tendency for the Fab/c to undergo redistribution and endocytosis when attached to viable cells incubated at 37 °C for 30 min: subsequent staining by fluorescein-labelled sheep anti-rabbit IgG at 0 °C showed the Fab/c to be distributed uniformly over the cell surfaces.

The Fab/c derivatives retained the ability to invoke complement-mediated lysis of target cells, whether by guinea pig or rabbit complement. Moreover they showed no tendency to induce antigenic modulation. Figure 2*a*, *b* shows the levels of cytotoxicity induced by IgG and Fab/c of anti-λ specificity for a range of concentrations. Preincubation at 37 °C with the IgG, but not with the Fab/c, induced modulation. Note also that Fab/c induced higher levels of cytotoxicity than IgG even in experiments lacking the modulating preincubation. This difference was more marked when guinea pig comlement was used, and is consistent with other evidence[3] that some modulation can occur when cells are confronted simultaneously by IgG antibody and complement at 37 °C.

The findings using IgG and Fab/c from anti-Id (Fig. 2*c*, *d*) were similar. However, note that modulation by the IgG for rabbit complement was less effective than in the case of anti-λ; that IgG antibody titred out further for rabbit complement than did Fab/c; and that the superiority of Fab/c over IgG for lysis by guinea pig complement was again apparent.

The therapeutic efficacies of IgG and Fab/c from anti-Id serum were assessed by inoculating strain 2 guinea pigs with L_2C leukaemia, then injecting them once with the test substance 24 h later, and observing survival (Fig. 3). Our tumour line has a doubling time *in vivo* of ~19 h, thus a simple kinetic model suggests that 50% killing of the tumour will prolong life by this time period. The complexity of events occurring *in vivo* introduces considerable uncertainty, but evidently the greater the cell kill from a single therapeutic event, the greater the subsequent average survival, with the duration of survival permitting some tentative inferences about the extent of killing. By increasing average survival by 10 days Fab/c was much more effective than the parent IgG (3.2 days), and in fact much more effective than any of our previous attempts at antibody therapy.

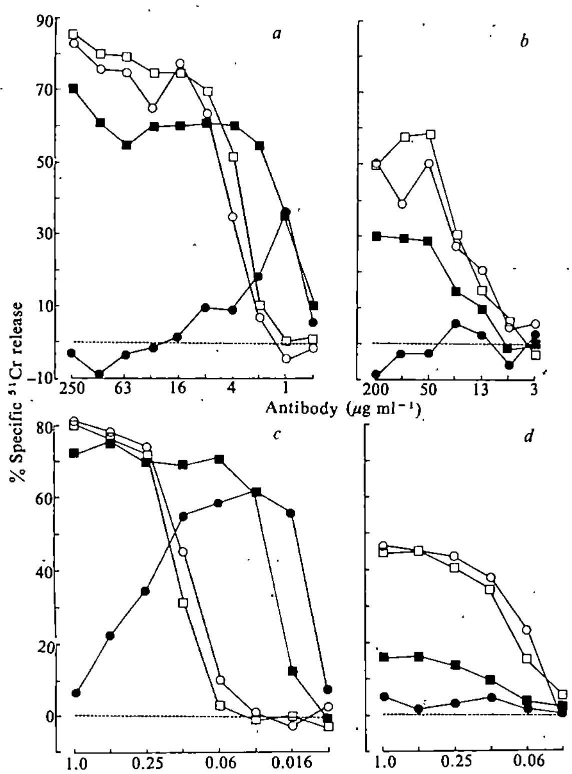

Fig. 2 Complement lysis of L_2C cells invoked by Fab/c (○, □) or IgG (●, ■) from purified anti-λ(*a*, *b*) or anti-Id serum (*c*, *d*). Complement was from rabbit (*a*, *c*) or strain 2 guinea pig (*b*, *d*). First the cells were labelled with ^{51}Cr and washed. To permit modulation they were incubated at $5\times10^5\ ml^{-1}$ with antibody derivatives at the indicated concentrations at 37 °C for 15 min (○, ●); control incubations were at 0 °C (□, ■). All suspensions were placed in an ice bath; 1.5 vol of a 1:2 dilution of fresh serum was added as a source of complement, and the temperature was raised to 37 °C for 30 min to promote complement activity. Finally the suspensions were chilled and the supernatants separated for assay of released ^{51}Cr. Methods are described in detail in ref. 19.

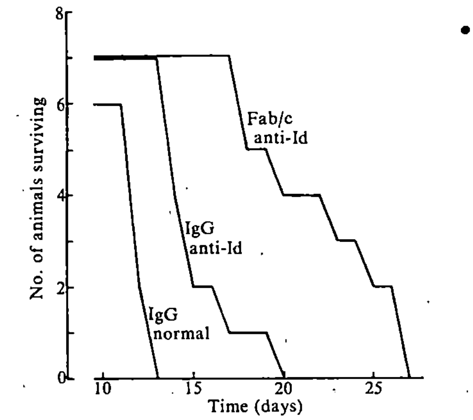

Fig. 3 Immunotherapy with Fab/c or IgG from anti-Id serum. Groups of guinea pigs were inoculated intraperitoneally (i.p.) with 10^5 L_2C cells (day 0). After 24 h they were injected i.p. with 10 mg IgG from normal sheep serum (6 animals), 10 mg IgG from anti-Id serum (7 animals), or 10 mg Fab/c derivative of the anti-Id IgG (7 animals). Animals treated with IgG (anti-Id) survived longer than those treated with IgG (normal), as did those treated with Fab/c (anti-Id) compared with IgG (anti-Id)-treated animals ($P<0.005$, χ^2 test[20]).

We have not yet defined the relative involvements of the classical and alternative complement pathways in the cell lysis invoked by IgG and Fab/c. Activation of the classical pathway by Fab/c would be further evidence against the possibility that steric changes in the IgG molecule consequent on both Fab arms being engaged are necessary for the binding and activation of complement component 1 (C1) (reviewed in ref. 14). The alternative pathway acts as an amplifier after activation of the classical pathway, and apparently acts independently in the lysis of certain virus-infected cells by antibody and complement[15]. The fact that bivalent antibody was required in the latter studies makes it unlikely that Fab/c invokes a similar mechanism.

The clear superiority of Fab/c over IgG antibody in invoking lysis by homologous (guinea pig) complement confirms the importance of antibody bivalency in permitting mammalian cells to escape from antibody-mediated destruction. Eluding this escape mechanism appears to offer a surprisingly simple means of enhancing the attack of antibodies on tumour cells. We are now evaluating Fab/c and similar derivatives of anti-idiotype antibody in the treatment of human chronic lymphocytic leukaemia, where the cells show some susceptibility to cytotoxic atack by anti-idiotype IgG[16].

Homocopolymer sequences in the spacer of a sea urchin histone gene repeat are sensitive to S_1 nuclease

Christopher C. Hentschel*

Institut fur Molekularbiologie II der Universitat Zurich,
Honggerberg, 8093 Zurich, Switzerland

The concept of specific functional elements in genes comprising localized or transient structural discontinuities, such as Z-DNA or cruciforms, is becoming increasingly plausible[1–6]. Cruciforms were first detected as supercoil-dependent single-strand nuclease (S_1)-sensitive sites characterized by hyphenated inverted repeat DNA sequences[2,3]. Here I describe examples of a novel type of S_1 nuclease site found in a sea urchin histone gene repeat and characterized by homocopolymer sequences. Endonucleolytic cleavage within these sequences does not depend on supercoiling, is highly sensitive to the salt concentration and shows a reproducible pattern of maxima and minima. This type of S_1 sensitivity may reflect the potential for out-of-register DNA slippage in such sequences and I speculate that related slippage events *in vivo* could lead to their acting as foci for recombinational events.

Recombinant plasmids containing either one copy of the 6.25 kilobase (kb) *Psammechinus miliaris* histone gene repeat h22 (refs 7, 8) inserted in the *Hin*dIII site of pBR322 (ref. 9; pBRh22/3), or a head-to-tail dimer of the repeat (pBRh22/4) similarly inserted, were digested with low levels of the single-strand-specific endonuclease[10] S_1 in conditions which linearized supercoiled pBR322 alone[2,3]. Surprisingly these plasmids were not only linearized but yielded discrete excision products indicating the presence of at least one supercoil-independent S_1 site (Fig. 1 *a*, *b*). In addition, the pattern of excision products bore no relation to A+T-rich stretches or inverted repeats in the DNA sequence. Previous studies have only detected specific S_1 sites in 'duplex' DNA, either at inverted repeats in supercoiled molecules[2–4], or in conditions which partially denature A+T-rich regions (for reviews, see refs 5, 6).

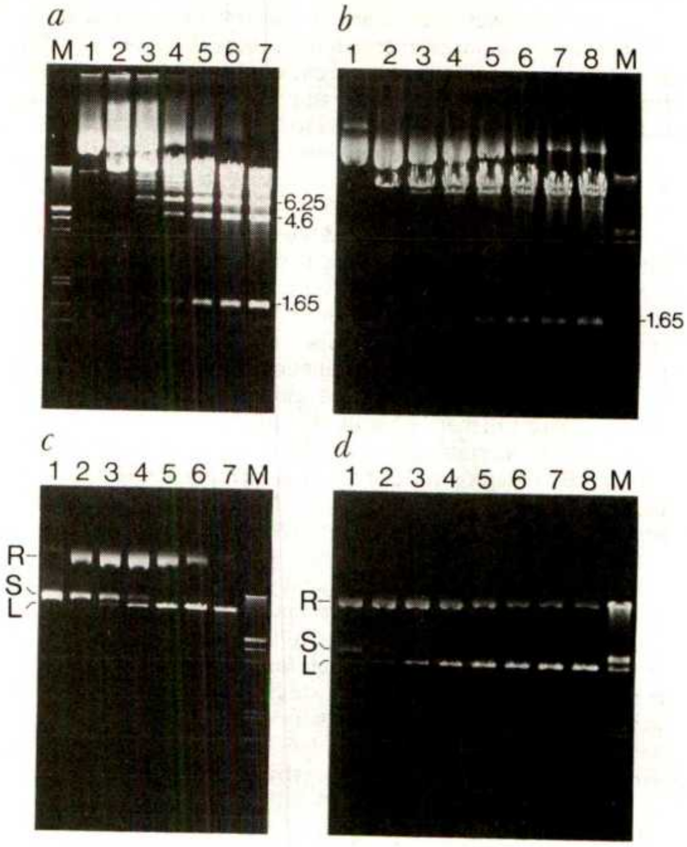

Fig. 1 Effect of S_1 nuclease on four plasmids analysed by 1% agarose gel electrophoresis; *a*, pBRh22/4, a recombinant containing a head-to-tail dimer of the 6.25 kb *Hin*dIII-cut histone repeat h22[7], inserted into the *Hin*dIII site of pBR322[9]; *b*, pBRh22/3, identical to pBRh22/4 but with only one histone repeat; *c*, a derivative of pBRh22/3 lacking the *Hpa*I fragment indicated by a thick line in Fig. 2*c*; *d*, pBR322. Lanes marked M are λ/*Hin*dIII/*Eco*RI size markers[26]. Other lanes are time points of S_1 nuclease digestion (lanes 1–8, respectively, 0, 2, 4, 8, 16, 32, 64 and 132 min). S_1 nuclease, prepared according to Vogt[10], was used at a concentration of 50 Vogt units per ml in 30 mM NaAc *p*H 4.6, 30 mM NaCl, 1 mM ZnCl at 37 °C. Electrophoresis buffer was 100 mM Na/glycine *p*H 8.5 containing 0.5 μg ml^{-1} ethidium bromide for UV photography[27]. For the smaller plasmids (*c*, *d*), the supercoiled (S), relaxed or nicked (R) and linear (L) forms are indicated. Sizes are in kb.

At the S_1 nuclease concentration used (see Fig. 1 legend), there was little background smear from random cleavage at A+T-rich regions but only 'partials' of the specific cleavage reactions were produced. It is nevertheless clear that whether one or two copies of the histone gene repeat is present, a 1.6 kb fragment is always excised. A 6.25 kb repeat length fragment and a 4.6 kb fragment (which together with the 1.65 kb fragment sums to the repeat length) appear only with the dimer insert (Fig. 1*a*). These results are consistent with the presence of only two major S_1 sites in the histone repeat sequence, 1.65 kb apart. Furthermore, as no excision products resulted from identical S_1 digestion of a 'mutant' plasmid lacking the *Hpa*I fragment spanning the H2A coding region and the H2A–H1 spacer (Fig. 1*c* and map in Fig. 2), one of the sites was tentatively located within this region of the histone gene repeat. The mutant plasmid was linearized at the second histone repeat site faster than pBR322 alone (Fig. 1*d*; mapping data not shown).

To locate exactly the two major S_1 sites on h22, S_1-cut pBRh22/3 and pBRh22/4 were secondarily restricted with several enzymes. These double digests mapped the S_1 sites in the spacers flanking the H1 gene. As anticipated, one of the sites lay within the *Hpa*I fragment and the other 1.65 kb downstream (see map in Fig. 2); this was confirmed by purifying the 1.65 kb S_1 excision product and restricting it with either *Bam*HI, yielding 900 and 750 base pair (bp) fragments, or *Bgl*I, yielding 850 and 800 bp fragments (Fig. 2*a*). These fragments are less clearly defined on the gel than the marker restriction fragments, suggesting that the S_1 cut ends are heterogeneous. Such heterogeneity is perhaps not surprising because the DNA sequences to which they map comprise the simple repeat motifs 5′(CA)10(CT)22 [site S_1 (a) in Fig. 2; P. Bucher, unpublished results] and 5′(GA)16 [site S_1(b) in Fig. 2; ref. 7]. The S_1(b) site is so close to the *Hin*dIII site downstream of the H1 gene (Fig. 2*c*) that when the *Hin*dIII-excised repeat is S_1-cleaved again, cutting at this site is not easily discernible, although it does take

place at a significant level (data not shown). However, partial cleavage at the S_1(a) site within this linear molecule is easily demonstrable and results in the production of 1.75 and 4.5 kb fragments (Fig. 2*b*). Thus cutting at either S_1(a) or (b) does not strictly depend on supercoiling, although an effect on the cutting rate has not been excluded. Moreover the larger S_1(a) site seems to be inherently more S_1 sensitive, at least in linear molecules (Fig. 2*b* and data not shown).

The observation that the homocopolymers flanking the H1 gene constitute novel S_1-sensitive sites prompted an examination of the possible mechanism involved. Because the S_1 activity is independent of DNA supercoiling, models based on the formation of unpaired regions in structures such as cruciforms[2–4], stabilized by torsional stresses, can be excluded. Moreover, unlike supercoil-dependent S_1 sites[2], the S_1 cleavage at the homocopolymers is highly sensitive to salt concentration: excision of the 1.65 kb fragment is strongly inhibited at 120 mM Na^+, close to the optimum salt conditions for S_1 activity, and is all but abolished at 300 mM, a concentration at which most of the intrinsic S_1 activity still remains[10,11] (Fig. 3). As duplex stability is directly proportional to the logarithm of total salt concentration[12], this result strongly implies that the S_1 sensitivity of the homocopolymers reflects a pre-melting phenomenon specifically associated with such simple repeated sequences[13].

A possible explanation, based on studies with pure homocopolymer preparations[13], is out-of-register DNA slippage with the production of single-strand loops flanking the slipped segment. Such structures would be expected to exist transiently. This notion is supported by examination of the distribution of nucleolytic cleavage within the homocopolymer sequences. For Fig. 4*a*, S_1-cut, ^{32}P-end-labelled pBRh22/4 was secondarily cleaved either with *Bam*HI (as a control to establish that label was incorporated in the anticipated 900 and 750 base fragments adjacent to the two S_1 sites; lane 1), or with the frequent cutting enzymes *Hae*III (lane 2), *Alu*I (lane 3) or *Taq*I (lane 4). The fragments were displayed on a sequencing gel and autoradiographic examination of the gel reveals the double digestion products expected from the S_1 site map (Fig. 2*c*) and the restriction map[1]. Note that the gel fails to resolve the terminal heterogeneity of the S_1-cleaved ends of the larger fragment but the smaller (≤200 bp) fragments are clearly resolved in a manner reflecting the nucleolytic cleavage pattern within the homocopolymers. Thus for the S_1(b) site, this pattern is bimodal and cutting is largely restricted to within a stretch of ~20 nucleotides (bracketed in Fig. 4). Figure 4*c* shows the sequence around S_1(b) with the relevant restriction sites and the deduced pattern of S_1 cleavage within the 5′(GA)16 motif. Thus, for example, *Taq*I restriction (Fig. 4*a*, lane 4) produces only one group of small terminal fragments (65–85 bases long), which can be seen to map from the *Taq*I site (■; Fig. 4*c*); similarly the *Alu*I site (●) maps the 95–115 base fragments. In fact all the bands shown in Fig. 4*a* can be mapped from an appropriate restriction site to either S_1(b) or S_1(a), although in the latter case the fragments are generally larger due to the paucity of restriction sites in the H2A–H1 spacer[1] (sequence not shown).

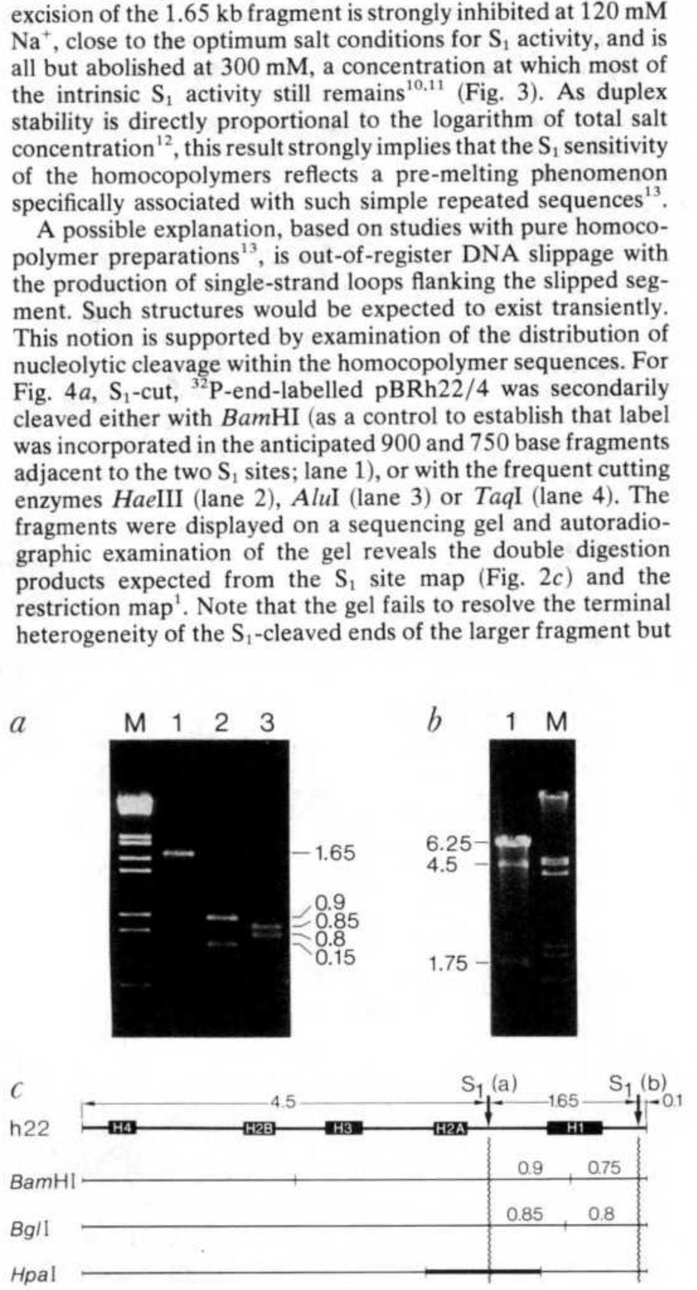

Fig. 2 Restriction enzyme mapping of S_1 cleavage sites. *a*: Lane 1, purified 1.65 kb S_1 excision fragment; 2, *Bam*HI restriction products of the 1.65 kb fragment; 3, *Bgl*I restriction products of the 1.65 kb fragment. *b*: Partial cleavage of *Hin*dIII repeat of h22 with S_1 nuclease using the conditions described in Fig. 1 legend with digestion for 1 h. The electrophoretic analyses were as for Fig. 1 except that for *a*, 2% agarose was used. *c* Is a map of the h22 repeat showing the deduced S1 site map relative to the restriction map[1].

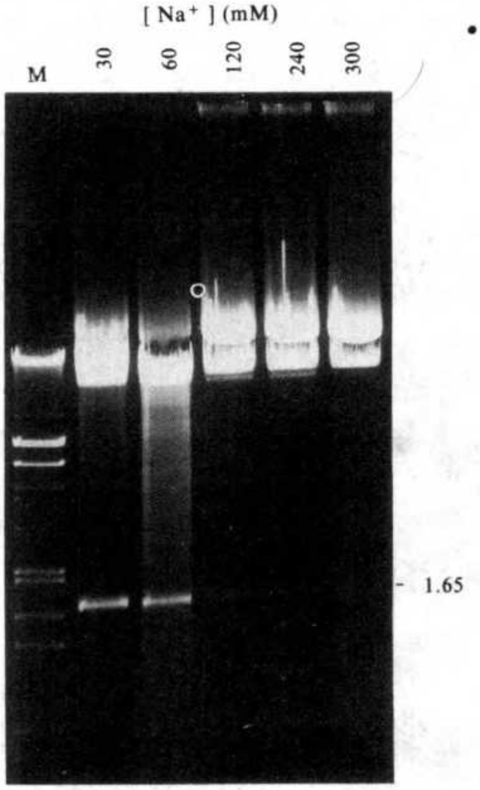

Fig. 3 Salt sensitivity of S_1 cleavage. pBh22/3 was digested with S_1 for 32 min with conditions and electrophoretic analysis as for Fig. 1 except that the NaCl concentration was adjusted to bring the total Na^+ concentration to the values indicated. The degree of S_1 cleavage can be judged by the production of the 1.65 kb excision product.

A bimodal cleavage pattern would be expected from a single predominant type of DNA slip as this creates two single-strand loops adjacent to the slip, each a potential S_1 target. This seems to be compatible with the S_1(b) pattern where the site comprises a simple homocopolymer. The cleavage fragments mapping to the S_1(a) site show a more complex pattern, approximately trimodal with a predominant central cleavage region covering ~40 nucleotides (flanked by a wavy line in Fig. 4). This greater length and complexity may be a time-averaged reflection of the many slipping modes possible within a long dual homocopolymer such as the S_1(a) site (5′(CA)10(CT)22). Figure 4*b* illustrates an alternative 'fine mapping' strategy. The purified 1.65 kb S_1-excised fragment was ^{32}P-end-labelled[14] and the derived *Bam*HI fragments (Fig. 2*a*) subjected to total chemical cleavage at either pyrimidine (lanes 1, 3) or purine (lanes 2, 4) nucleotides. Since the 5′-end-label lies almost exclusively in C-T runs for both *Bam*HI fragments, pyrimidine cleavage yielded no oligonucleotides when analysed on a 20% acrylamide gel (Fig. 4*b*, lanes 1, 3). In contrast, purinolysis mapped the S_1 cleavage pattern from neighbouring purine nucleotides (Fig. 4*b*, lanes

2, 4). Figure 4*b* reproduces almost exactly the complex multimodal pattern previously seen for the S_1(a) site extending over about 40 nucleotides, and the bimodal pattern for S_1(b) extending over about 20 nucleotides (cf. Fig. 4*a*). Note also that these map identically on the sequence (the purines from which to map the S_2(b) pattern are complementary to the 5′TT in Fig. 4*c*).

Whatever the physical basis for the S_1 nuclease sensitivity of the homocopolymers flanking the H1 gene of the h22 histone gene repeat, it is tempting to speculate about the possible biological significance of the localized DNA unpairing implied by these results. Homocopolymer sequences are found not only in the h22 repeat, but also adjacent to histone genes in several species (not necessarily the H1 gene)[8], the sequence 5′(CA)31 has been found ~300 bases downstream of the coding sequence of two immunoglobulin genes[15], and 5′(TG)17 has recently been found in an evolutionarily conserved repeat family in, for example, the 'spacer' separating the human δ- and β-globin genes[16].

Fig. 4 Fine mapping of nucleolytic cleavage sites. *a*: Autoradiograph of 8% acrylamide/urea gel[28] of fragments derived by secondarily cutting S_1-digested 5′ ^{32}P-end-labelled pBh22/4 (ref. 14) with the following enzymes: lane 1, *Bam*HI; lane 2, *Hae*III; lane 3, *Alu*I; lane 4, *Taq*I. The size marker (in bp; M) is a *Hpa*II-cut derivative of pBR322 (ref. 29). Note that in these experiments there are eight labelled ends which would be expected to yield four predominant labelled fragments assuming that nearly all the initial S_1 cleavage occurred as indicated in Fig. 2. Thus *Bam*HI should yield fragments 750 and 900 bases long (barely resolved in lane 1) and 2.1 and 2.3 kb (not resolved; see Fig. 2*c*). All the radioactivity is in the expected region of the gel and the sizes were confirmed on an agarose gel (not shown); most important, however, no 'unexpected' low molecular weight fragments are present, thus the heterogeneous bands in lanes 2–4 must derive from the anticipated double digestions. The heterogeneous fragments derived from cleavage at S_1(b) are shown bracketed, while those from S_1(a) are flanked by a wavy line. *c* Shows the sequence for the S_1(b) site in 50 base blocks with the relevant restriction sites (for *Taq*I, *Alu*I *Hae*III) and the deduced regions of maximal cleavage indicated by overlining. *b* Shows an alternative 'fine mapping' strategy. An aliquot of the same purified 1.65 kb fragment shown in Fig. 2*a* was 5′ ^{32}P-end-labelled[14], and the derived *Bam*HI fragments (Fig. 2*a*, lane 2) purified. Each fragment was divided into two aliquots which were either totally hydrolysed at purine nucleotides with formic acid/diphenylamine reagent (lanes 2, 4) or at pyrimidine nucleotides by hydrazinolysis (lanes 1, 3), and then purified as for sequencing reactions[14]. The purified products were analysed by autoradiography following electrophoresis on a 20% acrylamide/urea gel[14]. The products from the 900 bp fragment mapping the S_1(a) sites are in lanes 1 and 2, while those from the 750 bp fragment mapping the S_1(b) site are in lanes 3 and 4. Size marker as in *a*.

The homocopolymer sequences of the histone genes are located in spacer regions not known to have a direct effect on the expression of the genes[8], but which have been strongly implicated in evolutionary behaviour[17]. Although histone genes are usually clustered or tandemly repeated, the copy number, order and polarity of the genes vary widely between species and, in some cases, even within a single genome. Where the copy number is high, as in sea urchins or *Drosophila*, tandem repetition is the norm but escaped 'orphon' histone genes arise with a high frequency[18]. Subtypes of H1 genes arise at a particularly high frequency (see reviews in refs 8, 17, 19, 20, 13–15 and refs therein). All these facts suggest that mechanisms exist which allow occasional histone genes (and in particular H1 genes) to transpose, replicate and diverge independently. Could *in vivo* excision events at homocopolymers be involved in such mechanisms?

The rectification mechanism maintaining the homogeneity of tandemly repeated histone genes may also involve the homocopolymers because they could provide foci for unequal crossover or gene conversion events[17]. Although the exact nature of such recombinations is unknown, they would probably be facilitated by a potential for localized unpairing in these sequences. Moreover, the possibility that such unpairing reflects DNA slippage and that similar slippage may occur *in vivo* is supported by the fact that several biological phenomena are best explained by this mechanism: frequent frameshift mutations in the T4 lysozyme gene[21], mutational hotspots in the *Lac*I gene of *Escherichia coli*[22] and small deletions in human globin genes[23]. In addition, other specific recombinational events, such as globin gene conversion[24] or immunoglobulin class switching[25], are also thought to occur at simple repeated sequences. All these events could be related to a fundamental tendency for DNA slippage at such sequences.

I thank Professor Max Birnstiel for initially suggesting the DNA slippage mechanism, Bill Folk and Mary Bendig for discussion and critical reading of the manuscript, and Fritz Ochsenbein, Bonnie Bryan and Jackie Hardwick for help in its preparation. This work was supported by a grant from the State of Zurich and by Swiss NRF grant 3/257.077.

Magma chamber profiles from Bay of Islands ophiolite complex

CASEY and Karson[1] have presented a model for the shape and size of magma chambers underlying mid-ocean ridges, based on observations of the Bay of Islands ophiolite They show that igneous layering in rocks of the plutonic complex is oriented up to 90° oblique to the palinspastic horizontal, and they use this, and other evidence, to infer that nucleation and growth of crystals occurred *in situ* on the chamber walls, without the need for settling of crystals

The magma chamber model of Casey and Karson (Figs 4 and 5 of ref 1) shows a curious, unexplained and yet crucial feature, namely that while ultramafic rocks were forming along the sides of the chamber near its base, mafic rocks were forming along the sides at higher levels Neither the effect of pressure nor that of volatile content on crystallization of the magma can be responsible for this difference If the ultramafic and the mafic rocks indeed formed in the same magma chamber, and if Casey and Karson are correct in saying that crystallization occurred only along the chamber walls, then the magma must have been stratified, with more mafic magma lying below less mafic magma, the 'Unit 2' rocks of the plutonic complex (interlayered mafic and ultramafic rocks) would then represent the junction between the two magma types, that is a zone of mixing

This inference that the magma was compositionally stratified agrees with that reached by Sparks *et al*[2] on the basis of the density variation in mid-ocean-ridge basalts

CASEY AND KARSON REPLY—Donaldson's comment that we have inferred the existence of chemical heterogeneity along the margin of the magma chamber which formed the plutonic complex of the Bay of Islands Ophiolite is perhaps an understatement We categorically stated that "the lack of lateral continuity of the fine-scale layering must be interpreted as the result of fairly significant changes in physico-chemical conditions on a scale approximated by the lateral continuity of the layering (~⩽50 m)" We also stated that "significant chemical zonation in the magma chamber" was reflected by the fact "that fine scale igneous layers (which define isochronous planes) strike obliquely across the contacts between major lithologic subdivisions of the plutonic section"

Donaldson has also suggested that this interpretation of chemical zonation is consistent with the work of Sparks *et al*[1] (and presumably Huppert and Sparks[2,3]) He has further postulated that the transition zone ('Unit 2') of the plutonic complex can be interpreted as a mixing zone between two distinct magma types Certainly, Sparks and his co-workers have clearly shown the weaknesses inherent in the arguments which lead to the emphatic statements that mafic magma chambers cannot become chemically zoned because of continuous convective overturn Based on the extent of lateral continuity of layering throughout the plutonic complex and other factors treated in the original paper, however, we do not believe that one can simply categorize two magma types The overall chemical and mineralogical zonation of the crystallization products within the plutonic complex seems to span the entire thickness of the plutonic section Previous geochemical studies[4–6] and unpublished data collected by us indicate that there is no sharp break in mineral compositions identified at the transition zone These data seem to indicate that at any single time, the margin of the chamber was in contact with magma of numerous and highly variable compositions The compositional range seems to depend on stratigraphic height within the plutonic section The transition zone simply marks the first appearance of plagioclase as a major phase within the plutonic section

Detailed mineral chemistry studies by our group will attempt to characterize the scale and degree of chemical variations along a single magma chamber profile Until such time, however, it is premature to suggest a simple model having just two magma types and a single mixing zone The chamber could be multiply stratified on a fine scale and consist of multiple mixing zones that need not have a steady-state position within the chamber The dimension of the chamber might also be conducive to local chaotic and laterally discontinuous chemical stratification These possibilities have not yet been tested by Sparks and co-workers because they have initiated their studies using simple two liquid models It is also not clear that pressure and volatile content of the magma should be overlooked or discarded as a possible cause for at least part of the chemical and mineralogical zonation until further work, especially trace element and isotopic studies, has been completed At present there is little evidence to substantiate Donaldson's simplistic model of just two magma types, field and geochemical evidence seems to favour a more complex multiple stratified model

K^+ depletion and Na^+ pump density

IT has been shown[1] that the skeletal muscles of K^+-depleted rats lose large quantities of K^+, gain Na^+, and many have fewer ouabain binding sites than normal, this is in contrast to the findings of Chan and Sanslone[2] and Erdman, Bolte and Luderitz[3] for red blood cells (RBCs) and heart muscle, respectively, of K^+-depleted rats and in cultured human cells grown in low-K^+ medium[4,5]

In our original experiments we showed[4] that more pumps were produced in cells when the internal Na^+ concentration ($[Na^+]_i$) was allowed to rise to 20–60 mM, with a corresponding drop in $[K^+]_i$ In recent experiments we have found that very large increases in $[Na]_i$ (and correspondingly large reductions in $[K^+]_i$) lead to a large loss of ouabain binding sites and transport capacity in HeLa cells (Table 1) These losses in ouabain binding sites are greater than can be accounted for by cessation of the normal insertion rate of new pumps (1 5% h^{-1})[6] and imply that an accelerated removal of pumps is occurring

Our results show that HeLa cells can be made to produce either a greater or lesser density of pumps than normal, apparently depending on the ion concentrations within the cells, they therefore mimic RBCs and heart or skeletal muscles of K^+-depleted rats We suspect that two processes are occurring (1) as $[Na]_i$ rises, the rate of insertion of new pumps increases, and (2) if $[K]_i$ falls below a critical level, the synthesis of new pumps stops (because K^+ is required as a cofactor by most enzymes[7]) and pumps are

Table 1 Effect of changes in extracellular K^+ on the intracellular Na^+ and K^+ concentrations and on the specific ouabain binding of HeLa cells

removed from the membrane (by affecting the anchoring process?)

It is possible that the mechanism controlling the density of Na^+ pumps in skeletal muscle is no different from that in other cells, but that the ion concentrations achieved by any reduction of serum $[K^+]$ differ This could be investigated further by looking at the effects of smaller reductions of serum $[K^+]$ on the ouabain binding and $(Na^+ + K^+)$ATPase of rat skeletal muscle

Control cells had a $[Na]_i$ of 16 mmol l^{-1} and a $[K]_i$ of 179 mmol l^{-1} The $[K]_0$ values are the initial and final values (where measured)

NØRGAARD *ET AL* REPLY—Our observation that K^+-depletion in mice and rats leads to a progressive decrease in the number of ^3H-ouabain binding sites in skeletal muscle[1], does not agree with the results of previous investigators, who found that K^+ depletion increases $(Na^+ + K^+)$ATPase and the number of ^3H-ouabain binding sites in erythrocytes[2,3] as well as $(Na^+ + K^+)$ATPase activity in guinea pig hearts[4,5] Our observation that erythrocytes of K^+-depleted rats maintain normal K^+-contents even after weeks of exposure to the low plasma K^+ values agrees with the existence of a compensatory rise in their number of $(Na^+ + K^+)$ATPase units The reported measurements[4,5] of $(Na^+ + K^+)$ATPase activity in hearts used a sediment obtained by centrifugation of homogenates, and as this may contain only a minor fraction of the total $(Na^+ + K^+)$ATPase activity present in the starting material (for discussion, see ref 6), the results depend on the recovery being the same for hearts from normal and K^+-depleted animals

To explore this problem further, we have recently measured the binding of ^3H-ouabain to rat heart ventricles *in vivo* In the controls we found 276± 8 pmol per g wet wt, and 157± 18 pmol per g in the K^+-depleted rats ($P < 0\ 001$) This decrease (43%) is smaller than that found in skeletal muscle, which agrees with the observation that the loss of K^+ was not so pronounced in the heart Measurements of the ^3H activity in the plasma after intraperitoneal injection of ^3H-ouabain gave 77% higher values in the K^+-depleted rats than in the controls This also suggests that the peripheral binding capacity for ^3H-ouabain is reduced and that in the K^+-depleted state the heart may be exposed to a higher concentration of digitalis glycosides

At variance with the results obtained using HeLa cells[7], even modest K^+ loss (and a corresponding rise in intracellular Na^+) is associated with a decrease in the number of ^3H-ouabain binding sites in rat skeletal muscle (see Figs 1, 2 of ref 1) This suggests that the synthesis of new $(Na^+ + K^+)$ATPase units has ceased, and we are now investigating the possibility that this results from a general impairment of enzyme activity or protein synthesis

Despite our original expectations, we have been unable to detect any rise in the number of ^3H-ouabain binding sites in the muscles of K^+-depleted mice or rats It seems that skeletal and heart muscle cells differ from cultured cells, perhaps due to central regulatory mechanisms triggered by the drop in plasma K^+ seen a few days after the onset of the K^+-depleting regime The decreased capacity for active $Na^+ + K^+$ transport in muscle may prevent any further reduction in plasma K^+ and delay the development of the muscle paralysis which is the final outcome of prolonged K^+ depletion

The active radio galaxy 1413+135

BEICHMAN *et al*[1] and Bregman *et al*[2] present interesting IR and high-frequency radio (4 8–14 5 GHz) results on 1413+135 The latter also give an optical spectrum which suggests that it is a galaxy of redshift $z = 0\ 26$, no emission features were seen Curiously Beichman *et al*[1] imply that it was an 'empty field' until discovered as an IR source by Rieke *et al*[3]

The radio source was identified by Hoskins *et al*[4] with a 20 mag galaxy on the Palomar Sky Survey, and a finding chart was given The identification was based on 408-MHz measurements at Molonglo Condon *et al*[5] obtained an accurate radio position which agrees to 1 arc s with the optical position of Hoskins *et al*[4] This confirmed the identification but as Bregman *et al*[2] point out, the finding chart of Condon *et al*[5] is faulty Their positional offsets are also misleading Bregman *et al*[2] reconfirm the identification of Hoskins *et al*[4] but mistakenly refer to this as a 'PKS identification'

A radio spectrum covering the range 178–2,695 MHz is given by Murdoch and Hoskins[6] The low-frequency spectrum peaks at 3 Jy at ~300 MHz falling to 1 9 Jy at 178 MHz and 0 67 Jy at 2,695 MHz (in 1971) Bregman *et al*[2] report a strong and variable rise at 4 8 GHz and above and Beichman *et al*[2] show that the intensity peaks at ~100 GHz In addition to the highly compact component implied by these results, there is evidently a moderately compact component shown by the low-frequency radio data The overall radio spectrum is quite typical of BL Lac objects and highly variable QSOs The object would appear to be a galaxy with a BL Lac object in its nucleus

The ontogeny of phylogeny

David L. Hull

The Development of Darwin's Theory Natural History, Natural Theology, and Natural Selection, 1838–1859. By Dov Ospovat. Pp. 301. ISBN 0-521-23818-8. (Cambridge University Press: 1981.) £20, $39.50.

PUBLICATION is an unnatural event in the life of a scientific theory. Prior to publishing, a scientist can work in relative privacy, changing his views as he sees fit. After publication, however, the process is made more difficult by the critical stare of the scientific community. Darwin worked on his theory of biological evolution from 1837 until his death 45 years later. Historians have charted his intellectual voyage month by month, sometimes day by day — the *Beagle,* his decision to develop a theory of transmutation, his reading Malthus, the Sketch of 1842, the Essay of 1844, the receipt of Wallace's paper, the hurried publication of the *Origin,* and the trials and tribulations that followed. Ospovat retraces familiar ground in Darwin's story from 1838 to 1844 and then fills in the last gap — the period between 1844 and 1859.

Historians have ignored this period primarily because nothing much of any interest seems to have happened during these years. By 1844 Darwin had already decided that species evolve by chance variation and natural selection. The essentials of his theory were complete. Ospovat argues to the contrary that Darwin made several fundamental changes in his theory some time in the second half of 1856. Prior to that date, Darwin thought that every species is perfectly adapted to its environment, a belief that he carried over from natural theology. He considered that significant amounts of variation occur only in response to intermittent changes in the environment. As a result, evolution for Darwin at this stage in his development was "punctuational". However, in 1856 Darwin formulated his principle of divergence, a principle that he thought was as important as that of natural selection. According to this principle, variation exists within species at all times, allowing them to adapt to variations within their range, including the presence of other organisms. By a sort of "division of labour", species become subdivided into varieties, and these varieties are incipient species. From the beginning Darwin believed that evolution is in some sense progressive, but only after 1856 could he explain why the biosphere tended to become increasingly complex.

In 1855 A. R. Wallace published a paper on the law which regulates the introduction of new species, a paper that both Charles Lyell and Edward Blyth brought to Darwin's attention. Lyell urged Darwin once again to publish lest he be forestalled, and Darwin began his projected multi-volume *Natural Selection.* In 1857 Darwin and Wallace exchanged letters on Wallace's 1855 paper. Then Wallace's paper "On the Tendency of Varieties to Depart Indefinitely from the Original Type" (1858) arrived, not exactly like a "bolt out of the blue". What if Wallace's first paper had prompted Darwin to publish an "abstract" of his views in 1855? What if Wallace's 1858 paper had not caused Darwin to publish the *Origin?* What if Darwin had instead doggedly persisted in his original plan for his Big Book? Answers to such contrary-to-fact questions in history are extremely risky. Even so, Ospovat suggests that the *Origin* would have been a very different book had Darwin published it before formulating his principle of divergence. Instead of making the principle an integral part of his theory as first presented, Darwin would have been forced to introduce it later as an emendation. Similarly, he might have quietly passed on Wallace's paper for publication instead of agreeing to publish a short piece of his own along with it. If he had, I think that very little would have changed except later commentators would have been precluded from going on at such interminable length about Darwin's churlish behaviour. Darwin would still be viewed as the founder of the modern theory of evolution. The Darwin–Wallace papers of 1858 caused hardly a stir, Wallace's paper published alone is unlikely to have engendered more interest. But what of intellectual justice? From this perspective, Wallace still loses out, but this time to Patrick Matthew who had anticipated both Darwin and Wallace as early as 1831.

Although Ospovat makes the requisite passing remarks about the social, political and religious sources of Darwin's scientific views and concludes with a chapter on the development of Darwin's theory as a social process, his book is almost entirely an internalist history of the very best sort. Ospovat not only chronicles Darwin's conceptual development but also presents plausible reconstructions of the factors that led him to adopt the views he did. Not all of these factors are narrowly "scientific". For example, the tenacity with which Darwin held on to his belief in perfect adaptation stems at least in part from considerations that anyone, both then and now, would count as theological. Darwin was also influenced by prudential considerations of the sort that play a central role in the politics of science. For example, Ospovat argues that Darwin understates the progressive nature of evolution in the *Origin* for fear of offending Lyell and Huxley. But he does not repeat the usual facile claims about the direct translation of sociopolitical interests into the content of science.

Under normal circumstances, I would conclude this review by remarking that the appearance of *The Development of Darwin's Theory* portends a brilliant career for its author. Sadly, however, shortly after the completion of this manuscript, Dov Ospovat died at the age of thirty three. ☐

Red for green

H. McAllister

The Biological Aspects of Rare Plant Conservation. Edited by Hugh Synge. Pp. 558. ISBN 0-471-28004-6. (Wiley: 1981.) £30, $84.

DESPITE its title, most of this multi-authored book is very usefully devoted to the ways in which botanists in different nations work out which species and communities are in need of conservation in their own countries. As a result, the differences in the scale of the problem between the impoverished but well-known floras of north-western Europe, the rich, less well-known floras of such countries as South Africa, Australia and India, and the very rich, little-known tropical rain forest floras, are clearly brought out.

In north-west Europe the distribution and frequency of occurrence of most species is fairly well documented, so it is usually obvious which species are rare and in need of conservation The habitat requirements of such species are mostly known and several chapters deal with how sufficient autecological information has been obtained to devise successful conservation programmes

The conservation problems of north-west Europe pale into insignificance in comparison with those of such species-rich areas as the Cape of Good Hope with 1,244 threatened plant species Very few of these have been studied in any detail and the two species discussed exemplify the difficulties Field work undertaken to promote their conservation has demonstrated the importance of fire in stimulating germination, but, at least in the case of *Staavia dodii*, all attempts to germinate seed outside the natural field environment — including artificial fire — have failed, making garden cultivation impractical as a conservation measure The concentration of the few remaining populations of so many species in a small area poses serious management problems when so little is known of their autecology

However, by far the most critical situation exists in the tropical rain forests where a fair proportion of the species are still undescribed It can be reliably stated that if the present rate of destruction continues, and it is likely to, many species will become extinct before they can be described There is no doubt that this is the vegetation type in which most extinctions are taking place and that this is a loss not just to biological diversity but to the resources of the world of value to mankind The four chapters in Section 2 of the book, "Tropical Forests — The Conservation Priority", are an excellent statement of the problem and how it should be tackled The only sensible approach is to try to conserve areas of great species diversity and hope thereby to protect the maximum number of species Quite large areas may be required, as a typical tree species may have an average density of 1 per 5 hectares and be dioecious — though sometimes facultatively apomictic Dransfield's paper describes how controlled cropping can be compatible with conservation

One chapter, discussing the conservation of lower plants, points to the similarities with the situation in tropical rain forests — a lack of floras and lack of knowledge of species distributions, most species not being amenable to cultivation, meaning that conservation in their native habitats is the only hope for their survival

The varied topics covered make this work an excellent and much-needed world picture of the present state of plant conservation, although the quality of the individual contributions is very variable Unfortunately the book promises a bleak future, both environmentally and economically, if there is no improvement. □

Slimmer tracts for gut physiologists

G.J. Dockray

Physiology of the Gastrointestinal Tract, Vols 1 and 2 Edited by Leonard R Johnson Pp 1,492 ISBN 0-89004-440-6 (Raven 1981) Two-volume set $165

WHEN the American Physiological Society devoted a section of their *Handbook of Physiology* to the gut in the late 1960s, it needed five volumes containing well over 100 chapters to produce a comprehensive account of the subject After a period of unprecedented expansion in our knowledge of gut function it comes as a pleasant surprise to find that the present work consists of two volumes and less than half the number of chapters needed over a decade ago Unfortunately, the feeling of relief is tempered by the fact that this brevity has been partly achieved by a selective approach There is, for instance, relatively little attention given to the liver, salivary glands, comparative and evolutionary aspects, and control of nutrient intake The omissions are regrettable, not least because they are inimical to the editors' objective of producing a definitive treatise

This is not to say, however, that there are not good reasons to justify a relatively economical approach in reviewing the present state of gastrointestinal physiology Recent advances in this field have dealt very largely with the elucidation of events at the cellular and sub-cellular levels The present volumes both reflect the recent areas of progress and illustrate how it is possible to explain fundamental aspects of organization in a way that readily reconciles fragmentary and even contradictory work from the past

A series of chapters at the start of the first volume, and at the end of the second, deals with general aspects of digestive physiology and related topics The major gut functions — secretion, motility and absorption — are covered in separate sections In each case there are contributions dealing with functional morphology and molecular mechanisms, and these serve to provide a context for chapters dealing with the integrative aspects of each system The treatment works well, and in particular makes it easy to see how physiological mechanisms of the gut can be related to the functions of other organ systems Indeed, it is worth noting that a significant part of our understanding of such basic cellular mechanisms as membrane transport and secretion have been derived from studies on the alimentary tract and associated organs For this reason these two volumes will be of interest and value to many whose main concerns lie outside the gut, but who nevertheless wish to understand recent developments in gut physiology The gut chauvinist should not, however, feel neglected since there are, for example, chapters dealing with such singularly digestive subjects as dietary fibre and gut gas

The contributors are nearly all well-recognized authorities in their fields and most have taken the opportunity to produce a comprehensive assessment of the present state of their subject This, as much as anything, should serve to ensure the success and value of the work as a whole, since it is likely to be some time before such a strong team will again feel tempted to review their topics at length and in unison In the present climate of recession and austerity it would be surprising if there were many who felt inclined to buy this work for themselves, they need feel no guilt, however, about persuading their librarians to make the investment □

Cladistics clarified

Alan J. Charig

Phylogenetics The Theory and Practice of Phylogenetic Systematics By E O Wiley Pp 439 ISBN 0-471-05975-7 (Wiley 1981) £27 75, $49 90

WILLI Hennig is rightly regarded as the father of phylogenetic systematics, his book, *Phylogenetic Systematics* (University of Illinois Press, 1966) is the fundamental source of this important approach towards the reconstruction of evolutionary history and the classification of living organisms It is therefore appropriate that Wiley's new book on this subject should use a photograph of Hennig as its frontispiece During the last decade of Hennig's life (he died in 1976) the school of thought which he had founded — now loosely referred to as "cladistics" — attracted an ever-increasing volume of attention and comment

Within the last couple of years, however, the Hennigian school has sprouted the new, very different and even more controversial offshoot, "transformed cladistics" ("natural order systematics" in my terminology) The works of Popper on the philosophy of science undoubtedly exerted a major influence upon this schismatic development during its prolonged gestation, but Popper himself seems to have rejected it subsequently Indeed, were Father Hennig still alive today he too would have rejected it wholeheartedly, his arch-opponents would have been, not Mayr and Simpson, but leading transformed cladists like Nelson and Patterson

The approach of the transformed cladists is essentially typological, they maintain that there is a "natural order" in living things, manifesting itself in their aggregate similarity and not requiring to be interpreted as the result of evolution. They believe that time, evolution, genealogical relationships, the fossil record and the possibility of homoplasy have no part to play in systematics. Thus their philosophy is the absolute antithesis of Hennig's or Wiley's, in which — as is implied by the name phylogenetic systematics — phylogeny occupies a central position. Nothing could be more misleading than the recent pronouncement of a transformed cladist that Hennigian cladistics is merely "transformed cladistics with an evolutionary veneer". Contrary to general belief, the battle today is not between cladists and non-cladists but between transformed cladists on the one hand and, on the other, all those — be they followers of Hennig or of Mayr and Simpson — who maintain that the classification of living organisms should be based, wholly or at least in considerable part, upon the phylogeny.

Wiley is unashamedly an evolutionary or Hennigian cladist, he does not even mention transformed cladistics, for the very good reason that he must have written his book just before the new development made its overt appearance. On p. 98 he makes brief reference to the ideas of some workers, *circa* 1977, which foreshadowed the emergence of the new school, there is nothing more. Thus the volume reviewed here, unlike so much recent publication on the subject of cladistics, is concerned solely with Hennigian, i.e. evolutionary or phylogenetic cladistics.

Within that unavoidable limitation the book is first-class and might well be described as the evolutionary cladist's vade-mecum. The central part of the text is organized into five chapters — "Species and Speciation", "Supraspecific Taxa", "Phylogenetic Trees", "Characters and Reconstruction of Phylogenies" and "Phylogenetic Classification". The introduction which precedes it includes a great number of useful definitions clearly explained (although I myself do not agree with all of them) and discusses briefly the relationship of philosophy to systematics and the various approaches to scientific reasoning. Of the later chapters in the book, the first deals critically with the other major systems of taxonomy, the remainder are concerned with biogeography, specimens and curation (even a few pages on field-work and a couple of paragraphs on computer cataloguing), characters and their quantitative analysis, and publication and the Rules of Nomenclature. Bibliography and index run to over 18 pages each, the former providing an invaluable entrée into the literature.

The whole is arranged, set out and written with admirable clarity in excellent English. Compared with Hennig's exposition, Wiley's book is easy to find one's way around in; a remarkable amount of information and commentary on a comprehensive range of subjects is skilfully compressed into a limited amount of space, yet the author still manages to illustrate and emphasize his points by the extensive use of practical examples. Typographical errors are few. The book, nevertheless, is not without its faults. Thus the important aspect of cladistic analysis which everyone else (as far as I know) refers to as "polarity" is never called by that name and it took me a long time to track it down under the heading "Auxiliary criteria of phylogenetic apomorphy". Certain sections of the book with a mathematical flavour (for example those on Wagner algorithms and quantitative character analysis) were virtually incomprehensible to me, but that surely reflects my own innumeracy rather than any failing on the part of the author.

One of the most refreshing aspects of the book is that Wiley, although obviously a committed evolutionary cladist himself, does not assume the quasi-evangelical attitude so often adopted by his fellow cladists. (Just for the record, I myself am a firm believer in the rigour of a cladistic approach to phylogeny reconstruction but am strongly opposed to a purely cladistic classification.) Further, even more than the many other cladists who show healthy divergences of opinion on various points of doctrine, Wiley is no slavish follower of the majority, he shows a sturdy independence of thought, sometimes going so far as to recant on earlier statements of his own. Thus, unusually, he now accepts not only the postulation of ancestral species but also the possibility of occasionally recognizing them and of testing their hypothesized relationships.

I could make dozens of comments on this book, many of them highly favourable, but here are three of the other sort. First, perhaps because I am a palaeontologist, I deplore Wiley's uncompromising rejection of phyletic speciation into palaeospecies (allochronous speciation) and his consequent acceptance of each entire lineage as one species, irrespective of the amount of anagenetic change. (I note with pleasure, however, that Wiley — unlike Hennig — does not insist that the next dichotomy must inevitably terminate the species.) Secondly, I think it a great pity that he missed this opportunity to sort out the fearful confusion regarding the terms monophyly, polyphyly, holophyly and paraphyly once and for all — it is really so simple. And thirdly, I disagree with him profoundly on the alleged weaknesses of "evolutionary" (i.e. Simpsonian) taxonomy.

Notwithstanding such comments, I still feel that if a systematist were to be allowed only one work of reference on his desert island, he could not do better than choose Wiley's *Phylogenetics*. ☐

The Basel network

J.H. Humphrey

The Immune System, Vols 1 and 2. Edited by C. M. Steinberg and I. Lefkovits. Vol. 1 *Past and Future*, pp. 440, ISBN 3-8055-3407-8; Vol. 2 *The Present*, pp. 472, ISBN 3-8055-3408-6. (Karger: 1981.) Vol. 1 DM 297, SwFr 248, $148.50; Vol. 2 DM 321, SwFr 268, $160.50.

THESE two volumes comprise 125 essays written as a *Festschrift* for Niels Kai Jerne. They are a tribute not only to his seventieth birthday but also to his directorship of the Basel Institute of Immunology during its first ten years. The essays range from philosophical consideration of neurological processes and of art, through critical examinations of various current and earlier immunological hypotheses, to summaries of new experimental findings, mainly discussed in relation to their bearing on Jerne's own theories. Some are written by old friends and colleagues from his days in Copenhagen, Pasadena, Geneva, Pittsburgh and Freiburg, before he came to Basel, but the great majority are by colleagues who were members, students, visitors or even advisers at the Basel Institute.

The attraction of working at Basel was very great, since Jerne's policy was to have only a small core of permanent members but a much larger number of able, mostly young immunologists from all over the world for anything from six months to five years. He had a flair for choosing persons with talent who would return to work in lively departments elsewhere, and thus the list of contributors to the books reads rather like a selection from an immunological *Who's Who*. Most of them evidently felt challenged to write something original which would amuse or interest Jerne himself as well as any potential readership.

The outcome is as much as anything a view of the immune system as seen from Basel. Here the focus has been on the basic problems of how the immune system recognizes self from not-self, and how there arises the immense variety of different antibodies and receptors on T-lymphocytes which a frog or a mouse or a human being can make. This has involved study of the structure of monoclonal antibodies (initially from myelomas but later from hybridomas also) and of the mechanisms of their assembly and secretion, development of greatly improved culture methods, which made it possible to measure the number of lymphocytes able to respond to any given antigen, or to make immunoglobulin (Ig) in response to polyclonal mitogens, and, when cloning of DNA and DNA sequence studies became possible, comparison of the genes controlling the synthesis of specific antibodies with each other and with corresponding genes in the fetus, which led in Basel and elsewhere to the recognition of three separate genes controlling the variable region of Ig Since similar studies on the receptors of T-lymphocytes are frustrated by the difficulty of identifying, let alone purifying T-cell receptors, the variety of T-cells had to be approached by functional assays *in vitro* (mainly the generation of cytotoxic cells but also of helper and suppressor cells) using the improved culture methods developed in Basel to permit enumeration of single cells by limiting dilution assays Faith and hope are now being pinned on T-cell clones, with recognizable specificities, as a source of receptors which can be isolated and sequenced, with the aim of eventually identifying the genes controlling them and so discovering their relationship to the genes controlling Ig and the Ir region of the major histocompatibility complex

When, in 1974, Niels Jerne put forward the network hypothesis (which states that for every specific antibody or T-cell receptor which has a distinct combining site (idiotype), the immune system is likely to contain cells able to recognize that idiotype and, in principle, to respond by making more anti-idiotype — which in turn can stimulate cells making anti-anti-idiotype etc , and so establish an infinite network of interactions), some of his colleagues put it to the test. They found that in the special circumstance when mice respond to a bacterial antigen by making antibodies with predominantly a single idiotype, specific anti-idiotype antibodies could either stimulate or suppress antibody formation against the original antigen The network hypothesis was thus shown to have at least one real mesh, subsequent work on idiotypes has established several more, and a fair amount of the work going on in Basel (and of the more speculative essays in these volumes) is orientated towards the network hypothesis However since the Institute has a horizontal structure, in the sense that in principle no scientist can tell any other scientist what to do, aspects of immunology which profoundly affect the practical outcome of antigenic stimulation — such as lymphocyte recirculation and the role of macrophages — are also studied there, even though Jerne thought them irrelevant to the basic questions which he hoped to see answered

The volumes contain essays on all of these subjects, and even some rather good ones on non-specific factors, such as complement, by scientific advisers who reckoned that Jerne should recognize that they also are important The more speculative essays, with few or even no references, are included in the first volume and the harder science in the second

It may reasonably be asked what a collection of this nature has to offer to persons outside the charmed circle of Jerne's associates Since the contributors felt challenged to write something original, and since free speculation was encouraged and the personalities of the authors show through in their writing, the collection provides enough stimulation to satisfy any reasonably knowledgeable immunologist It would take a keen seeker after enlightenment to read through all of the 900 odd pages, but since the editors have grouped the essays under subject headings, selective browsing is quite possible I would expect to recognize the striking dust jacket (by Jean Tinguely) on train and aeroplane journeys, and even at the bedside □

J H Humphrey is a Professor in the Department of Medicine at the Royal Postgraduate Medical School, University of London

The second volume of *Elsevier's Dictionary of Botany*, edited by Paul Macura, has recently been published by Elsevier Scientific (For review of Vol I, *Plant Names*, see *Nature* **284**, 382, 1980) Volume II, *General Terms*, contains some 10,000 entries of English, French and German terms used in botany and associated disciplines, and includes French, German and two Russian indexes, one numerical and the other alphabetical The book costs Dfl 260, $110 75

Down and beyond the composite particle

M.G. Albrow

Jets of Hadrons. By W Hofmann Pp 210 ISBN 3-540-10625-1/0-387-10625-1 (Springer-Verlag 1981) DM 62, $28 20

THE study of strongly interacting particles (protons, neutrons, pions etc) and the forces between them is no longer frontier physics We have passed beyond and down to the next layer It has become established beyond any reasonable doubt that these so-called particles are not elementary at all, but composites of more fundamental constituents The main effort in high-energy physics is now directed towards studying these constituents and the forces between *them* A vast amount of experimental information is all consistent with a theoretical framework describing these constituents as fractionally charged quarks and antiquarks which bind together by exchanging electrically neutral gluons These entities seem to be at the same level of elementarity as electrons, muons, neutrinos and photons, yet the latter are freely observed unlike quarks and gluons One can do an experiment (for example scatter a high-energy muon through a known large angle on a proton) which should produce a quark with a known energy and direction No quark is seen, always a shower of normal composite particles (hadrons) such as pions, kaons and so on Try harder by increasing, to the limit of present accelerators, the energy of the muon or the angle of scatter, and the showers become more collimated They are known as jets of hadrons

Our theoretical outlook has changed so much and the amount of experimental information has grown so rapidly in recent years that Hofmann's review of the field is extremely welcome To illustrate this rapid development most of the 400 papers in the reference list have been published in the past four years In such a situation the author must of course take the risk that the book becomes quickly dated If it does, I suspect that it will be due to the availability of more (and more precise) experimental data rather than to the concepts and the formalism becoming outdated

The book "is intended to give an introductory review to the phenomenon of jets in hadronic final states ", and the author succeeds admirably in fulfilling this intention Starting from the simplest situation of e^+e^- annihilation (where the massive virtual photon produced by the annihilation transforms to a $q\bar{q}$-pair, which in turn materializes as two jets), he leads the reader through jets in parton models and their development as quantum chromodynamics (the theory of quark–gluon forces) to the more complicated processes of hadron–hadron collisions A chapter on the old "uncorrelated jet model" and one on "soft" hadronic collisions are useful reminders of the importance of phase space effects and four momentum conservation, and also that while theory has a long way to go in describing the most common collisions there is encouraging progress in that direction

It is a pity that the author was not prepared to address the question of future developments Now that proton–antiproton collisions are being studied at CERN at energies nearly ten times higher than previously available at the ISR, and that LEP has received approval to study high-energy electron–positron collisions, a discussion of expectations for future experiments would have been a useful addition Nonetheless, this review is sufficiently detailed and complete that theorists working in the field will find it a valuable guide to the existing experimental data, and experimentalists will appreciate the exposition of the theoretical ideas It is, however, written at a level such that graduate students in high-energy physics should not find it too heavy-going, and it will familiarize them with what may well remain a major topic in the subject over the next decade □

M G Albrow, currently at CERN, is a Research Physicist at the Rutherford Appleton Laboratory, Chilton, Oxfordshire

BOOKS RECEIVED

Earth Sciences

HALLAM, A Facies Interpretation and the Stratigraphic Record Pp 316 ISBN 0-7167-1291-1 (W H Freeman 1981) £10 95

HOLMES, S C A Geology of the Country Around Faversham Geological Survey of Great Britain, England and Wales Memoir for 1 50 000 Geological Sheet 273 Pp 117 ISBN 0-11-884141-6 (Institute of Geological Sciences, London 1981) Np

MENARD, H W (Director) The Mississippian and Pennsylvanian (Carboniferous) Systems in the United States Geological Survey, Professional Paper 1110-M-DD Pp 572 (No ISBN) Government Printing Office, Washington 1981) Pbk np

MERRIAM, D F (ed) Computer Applications in the Earth Sciences An Update of the 70s Series Proceedings of the 8th Geochautauqua held October 1979 at Syracuse University, the Division of Marine Geology and Geophysics at the University of Miami, and The International Association for Mathematical Geology Pp 385 ISBN 0-306-40409-0 (Plenum 1981) $45

MOORE, W G The Penguin Dictionary of Geography Definition and Explanations of Terms used in Physical Geography 6th Edn Pp 256 Pbk ISBN 0-14-051-002-8 (Penguin 1981) Pbk £1 95

OLIVER, J E Climatology Selected Applications Pp 260 ISBN 0-7131-6303-8 (Edward Arnold, London 1981) £14 95

OZIMA, O The Earth Its Birth and Growth Pp 117 Hbk ISBN 0-521-23500-6, pbk ISBN 0-521-28005-2 (Cambridge University Press 1981) Hbk £10 50, pbk £3 95

RUDLOFF, W World-Climates with Tables of Climatic Data and Practical Suggestions Pp 632 ISBN 3-8047-0509-X (Wissenschaftliche Verlaggsgesellschaft MBH, Stuttgart 1981) DM 180

SMITH, C D and PARRY, M (eds) Consequences of Climatic Change Pp 143 Pbk ISBN 0-85358-022-7 (University of Nottingham 1981) £3 50, $10

SONNENFELD, P (ed) Tethys The Ancestral Mediterranean Benchmark Papers in Geology, Vol 53 Pp 331 ISBN 0-87933-355-3 (Academic 1981) $40

STOKES, W L Essentials of Earth History An Introduction to Historical Geology 4th Edn Pp 577 ISBN 0 13-285890-8 (Prentice-Hall 1982) $22 95

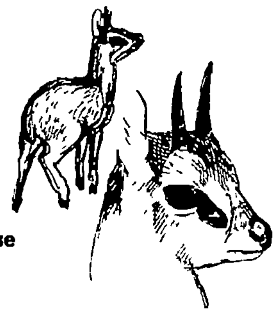
March 1982, vi+352pp, £49 95 (UK only)/$99.50. 0 12 408345 5



For fifteen years Jonathan Kingdon studied and portrayed the wildlife of Kenya, Uganda and Tanzania Since 1971 his work has been published in a series that has gained international acclaim as one of the most remarkable zoogeographical studies of our time — *East African Mammals* In successive volumes the primates, small mammals, and latterly large mammals, have been subjected to the exhaustive scrutiny of a dedicated observer Details of behaviour and anatomy undetected by the camera have been captured in exquisite and vital line drawings and sketches A wealth of information on physiology, distribution, social systems, habitat, ecology and evolution has been encapsulated in a penetrating and commanding text Taken individually, the volumes of *East African Mammals* provide the most comprehensive guides available for their particular subjects taken together they make up a treatise of immeasurable value, which is now complete with a two-part volume on the bovids

British Journal of CLINICAL PHARMACOLOGY

ESSENTIAL INFORMATION AT YOUR FINGERTIPS EVERY MONTH!

Published monthly on behalf of the British Pharmacological Society, *British Journal of Clinical Pharmacology* is as fast-moving as the area of science it examines

Bridging the gap between medical professions, clinical research and the pharmaceutical industry

Containing papers and reports on all aspects of drug action in man, in both health and disease

Providing free copies of the proceedings of selected symposia on new methods, new drugs and new approaches to treatment, to all subscribers

To keep up-to-date in this fast-moving area of science why not join the ever-increasing number of clinical pharmacologists all over the world who rely on the *British Journal of Clinical Pharmacology* as their professional journal

ANNUAL SUBSCRIPTIONS

UK £90
USA/Canada US$225
Rest of the world £110

Orders should be accompanied by remittance, cheques made payable to Macmillan Journals Ltd Subscription Department, Brunel Road, Basingstoke, Hampshire, RG21 2XS, England

Sample copies are also available from the same address
